Acknowledgements

This thesis would not exist without the support of my family, my supervisors and my friends. Lesley Gray and Scott Osprey offered me their help, guidance and kindness even before I applied to the DPhil. I am forever grateful for their help and support and that I was able to be part of their group and that I was able to learn from them. To Robin Chadwick, for always being willing to help me and provide very helpful advice and engage in discussions.

I would like to thank Philip Stier and Tim Woollings for reading my Confirmation and Transfer of Status reports. Similarly, my thanks go to Antje Weisheimer and Regina Rodrigues for examining my thesis and their helpful comments which have certainly improved this thesis. Many thanks as well for Zane Martin for useful discussions and support throughout this project. To Andrea and Lucy, for helping me navigate all the administrative processes.

My deepest gratitude goes to the Richard's family, which supported my studies at Oxford through the Oxford-Richards scholarship at Wadham College. Acknowledgements to Wadham College and Dr. Hanna Christensen for all their support and advice. To Andrew Bushell, Robin Chadwick and the UK Met Office for the PhD CASE Studentship I was awarded through the Met Office Partnership program which was key to support the science found in this thesis.

To my parents, Virginia and Jorge, that have always encouraged and supported me all along the way, all together. Thank you. Things would be very different without me crossing paths with all the Ambiguos: Karen, Pablo, Diego, Adán, Alinne, Montse, Carolina, Marcos and Dieguito. Thank you for always welcoming me back home. Special thanks to Karen Solorzano, Karen Ines and Pablo Bonilla for supporting me at a long distance throughout the difficult times. And to Verónica, for without your support this thesis would not exist. To everyone in Mexico and Leeds that helped me get here: Michel, Angel, Juliane, Paloma, Marcos and Melissa. I also wish to thank all the great friends I made in Oxford: Kate, Aaron, RJ, Oscar, Hank, Filippo, Matt and Emily.

Abstract

This thesis investigates the representation of the variability and teleconnections of the American Monsoon System in the state-of-the-art general circulation models. The models exhibit several biases including an overestimation of the strength of the East Pacific Intertropical Convergence Zone (ITCZ) and the position of the Atlantic ITCZ. The representation of the seasonality and magnitude of monsoon precipitation in the North American and Central American monsoons has improved compared to previous generations of the models, however, the spatial distribution of precipitation in the South American Monsoon is still poorly represented due to biases in the equatorial Atlantic sea-surface temperatures (SSTs)s. These simulations reasonably represent the seasonal cycle of precipitation in southern Mexico and Central America, where a bimodal signal known as the Mid-summer drought (MSD) has been important for agriculture in the region for centuries. A wavelet transform method is developed to diagnose the timings of the bimodal seasonal cycle and results illustrate that the method can diagnose monsoon timings in any monsoon region for any precipitation time series, including climate model output. Using this method, several theories that explain the existence and timing of the MSD signal in southern Mexico and Central America are evaluated using reanalysis and climate models. These results suggest that the MSD can be most consistently explained through the effect of seasonally varying moisture transport driven by the low-level flow in the Caribbean Sea. The influence of the quasi-biennial oscillation (QBO) teleconnections is explored in several climate model simulations, and the results suggest that the QBO could affect ocean-atmosphere phenomena. More frequent positive phases of El Niño-Southern Oscillation and the Indian Ocean Dipole, and a weaker Walker circulation are found during QBOW compared to QBOE in the models. Atmosphere-only and coupled ocean-atmosphere experiments are performed where the zonal winds in the equatorial stratosphere are specified, by relaxing them towards reanalysis data. The representation of the QBO is improved in these experiments, particularly in the lower stratosphere. However, the surface impacts of the QBO in the experiments with the relaxation result in a weaker tropical response to the QBO phase compared to the free-running models. These results imply that the relaxation has disrupted processes and/or feedbacks that are important for the surface impact of the QBO. The results of these experiments highlight the importance of SST feedbacks and the interaction of tropical waves with the zonal flow in the stratosphere for the interaction of the QBO on tropical convection.

Introduction

The American Monsoon System (AMS) is the main source of rainfall for most of Latin America and the southwestern United States, regions where agriculture is an important economic activity and a vast wealth of ecosystems and biodiversity are supported by monsoon rainfall in this region. Changes to the amount, timing and location of rainfall over different temporal scales have direct consequences for society and ecosystems. For that reason, improving our physical understanding of the mechanisms that cause temporal changes to the AMS rainfall is crucial to improve our medium-range forecasts and our climate predictions which could ultimately render key information for risk assessments, climate adaptation and agricultural strategies. In this context, this thesis aims to tackle outstanding questions of the AMS using a global climate model with a particular interest in better understanding the physical mechanisms associated with variability and teleconnections of this monsoon.

1.1 Motivation

Temporal and spatial variability of rainfall is important for society throughout the planet, but any short and long-term changes to precipitation are increasingly relevant in agriculturally active and biodiverse hotspot tropical regions (Sultan et al., 2005; Jain et al., 2015). In the AMS, variability on inter-annual scales, i.e., changes to amount or seasonality of rainfall from one year to the next, can produce long-lived droughts that are associated

with crop loss and forest fire intensification (Chen et al., 2009; Harvey et al., 2018). A large body of monsoon research is consequently focused on improving our understanding of the physical mechanisms responsible for precipitation variability across temporal and spatial scales (Wang et al., 2017; Gadgil, 2018).

The AMS was only recently recognized as a monsoon after the 1990s (Adams and Comrie, 1997; Zhou and Lau, 1998), as the definition for a monsoon has evolved from an initial dynamical definition based on the reversal of the prevailing winds to an agronomical definition that recognizes the seasonality of precipitation as the dominant feature of a monsoon (Wang et al., 2017; Gadgil, 2018). This means, however, that our understanding of the AMS is more limited compared to other monsoons given the lower number of studies on the AMS from a monsoon perspective compared to other monsoons such as the Indian monsoons, where monsoon forecasts exist since the 19th century (Blanford, 1886).

Recently, theories for monsoon dynamics (Bordoni and Schneider, 2008; Biasutti et al., 2018; Hill, 2019; Geen et al., 2020) have arisen to coherently explain the monsoons through a general physical mechanism. Most of these theories aim to explain a global inter-hemispheric band of convection that is driven by the seasonal cycle of solar insolation. Several characteristics of the North and South American monsoons, however, challenge the basic physical inferences or predictions of these theories, which means that these frameworks cannot readily be applied to the AMS. For this reason, several primary questions about the AMS remain open such as mechanisms and sources for the seasonal cycle (Turrent and Cavazos, 2009) and intra-seasonal (Perdigón-Morales et al., 2019) and interannual variability (Cai et al., 2020), the effect of greenhouse forcing on the monsoon dynamics (Liebmann and Mechoso, 2011; Pascale et al., 2019) and the role of soil-atmosphere interactions (Dominguez et al., 2008; Malhi et al., 2009; Adams et al., 2013). The main focus of this thesis is the first topic of the above, i.e., the physical mechanisms for inter-annual and seasonal variability and teleconnections pathways.

One prominent example of the lack of understanding of the basic physical mechanisms in the AMS is the puzzling seasonal cycle of rainfall in southern Mexico and Central America. The so-called Midsummer drought is a robust bimodal feature of the seasonal cycle of precipitation during the wet season that has had implications for agricultural practices

in the region since the Mayan Empire (AD 800-900) (Jobbová et al., 2018). Despite the importance of region-wide agricultural practices, the physical mechanisms that can explain this seasonal variation of rainfall remain disputed over recent years (Karnauskas et al., 2013; Herrera et al., 2015; Zermeño-Díaz, 2019). The topic of seasonal drought mechanisms in southern Mexico and Central America will be a central aspect of this thesis.

In contrast, a relatively well-known aspect of tropical climate is the El Niño-Southern Oscillation (ENSO), which is a coupled-ocean atmosphere phenomena in the Pacific Ocean that produces long-distance impacts throughout the planet (McPhaden et al., 2006), prominently influencing interannual variability in the AMS regions (Magaña et al., 2003; Vera et al., 2006; Marengo et al., 2014). Progress has been made in understanding the impacts and pathways of ENSO to South America (Marengo et al., 2012; Cai et al., 2020), and current research has found that diversity in ENSO events causes different impacts to South America (Hill et al., 2009; Tedeschi et al., 2015). A currently active topic of research aims to understand how impacts to the AMS depend on the interaction between ENSO and its teleconnections and other aspects of climate variability (Cai et al., 2019, 2020; Jimenez et al., 2021).

For instance, a growing number of studies have suggested a link between the stratosphere and the tropical troposphere, called stratospheric-tropospheric coupling (Haynes et al., 2021). This coupling is suggested to include tropospheric features such as ENSO and other modes of tropical variability (Hitchman et al., 2021; Martin et al., 2021b). There is no full description of the causes for these observed relationships yet, but if the stratosphere is found to be a relevant factor to modulate aspects of tropical convection, such as ENSO impacts, there would be an opportunity to better predict tropospheric variability because the equatorial stratosphere is generally predictable at longer time-scales than the troposphere. Stratospheric-tropospheric coupling will be another central topic of this thesis.

One key tool to understand the causes for regional changes to monsoon rainfall are general circulation models (GCMs). These models are useful to evaluate the roles of climate features such as orography, air-sea coupling, ENSO teleconnections and impacts, and also monsoons (Zhou et al., 2016). However, the use of GCMs to address key questions of the AMS has been scarce and detailed accounts of the biases –differences between the simulated climate of a model and the real world – are rarely done with explicit emphasis on the AMS.

In other words, GCMs are rarely evaluated in the AMS, so our understanding is deficient in the knowledge of the relevant biases in current GCMs and, therefore, GCMs are less frequently used to address scientific questions related to the AMS.

This thesis begins with an assessment of the mean state of the AMS in a state-of-the-art climate model in Chapter 4. This chapter showcases how this model may be used to increase our knowledge of the AMS, by investigating the seasonality of monsoons and bimodal regimes using a new method in Chapter 5 and the physical mechanisms for the seasonal cycle of southern Mexico in Chapter 6. The first result chapter also shows suggestive evidence that the stratosphere may play a role in ENSO impacts to South America, which leads to Chapter 7 which investigates whether there is any coupling between the stratosphere and the troposphere within the GCM.

1.2 Thesis aims and outline

The main aim of this thesis is to investigate the physical causes of variability and the mechanisms associated with teleconnections to the AMS. The specific key aims of this thesis are:

1. To characterize the large-scale biases in a state-of-the-art GCM that are relevant for the representation of rainfall in the AMS.
 - (a) To characterize the main biases in the thermodynamical and dynamical features over the large scale tropical domain and the regional AMS sub-domains.
 - (b) To evaluate the roles of large-scale biases, horizontal resolution and the use of Earth system processes for regional monsoon representation.
 - (c) To assess the representation of the teleconnection associated with the main driver of interannual variability, i.e., ENSO in a GCM with specific emphasis on the causes for non-linearity and non-asymmetry in the teleconnections.
2. Evaluate the seasonal variability of the monsoon onset, withdrawal and intra-seasonal changes in the GCM and compare to observational datasets.

3. Describe and investigate the physical mechanisms associated with the seasonal cycle of rainfall in Central America and southern Mexico by testing previous hypothesis of physical mechanisms within the model.
4. To investigate the role of stratospheric-tropospheric coupling in the tropics and the role of the tropopause for convection in the AMS and for ENSO teleconnections.

The remainder of this thesis is structured as follows:

- Chapter 2 provides a review of the literature on key aspects of the American monsoons. The chapter begins by introducing the concepts of monsoons, their different physical interpretations as a global phenomena and the place of regional monsoons in the global scale. Then, the North and South American monsoons are introduced and detail is given on the applicability of large-scale monsoon theories to these regional monsoons. This section is followed by a literature review of the proposed physical mechanisms that drive the seasonal cycle of rainfall in Central America, southern Mexico and the Caribbean. El Niño-Southern Oscillation impacts over North and South America and, finally, the chapter summarises the literature on stratospheric-tropospheric coupling in the tropics, discussing possible mechanisms by which the stratospheric quasi-biennial oscillation may be influential for tropical convection.
- Chapter 3 describes the observational datasets used in this thesis, composed of four gridded precipitation datasets and one reanalysis dataset: ERA5. The chapter also described the UK Met Office Hadley Centre Unified Model (UM) and the configurations of the UM used in this thesis and the Coupled Model Intercomparison Project phase 6 (CMIP6).
- Chapter 4 evaluates the representation of the AMS in three configurations of the UM model submitted to CMIP6. The chapter describes large-scale biases over the tropics and regional scale biases in the precipitation amount and seasonality in key regions of the AMS. ENSO teleconnections are also evaluated over the AMS examining the non-linearity of simulated and observed teleconnections and the role of ENSO flavours.

This chapter highlights relevant questions that are of interest to the wider AMS community that are tackled in the remaining chapters: first, the skill of the models in reproducing a bimodal signal in the seasonal cycle of rainfall in Central America and southern Mexico and second, a possible modulation of ENSO teleconnections by the stratospheric quasi-biennial oscillation. The majority of the work in this chapter has been published in *Weather and Climate Dynamics* as García-Franco et al. (2020).

- Chapter 5 details a wavelet covariant transform method used to diagnose the start and end of the rainy season in a monsoon using precipitation time-series. The method is extended to determine the timing of bimodal regimes, and even whether or not a bimodal regime exists or not in a given region. The method is illustrated in the North American and Indian monsoons, and for the Mid-summer Drought signals of the Caribbean and southern Mexico. This chapter has been published in the *The International Journal of Climatology* as García-Franco et al. (2021).
- Chapter 6 uses the wavelet method to investigate the physical mechanisms that cause the bimodal regime of precipitation in southern Mexico in the UM CMIP6 models. The chapter tests elements of three leading hypothesis for the Mid-summer drought, specifically the chapter examines the roles of the East Pacific sea-surface temperatures, the cloud-radiative effects and shortwave radiation and the Caribbean Low-Level Jet. Furthermore, the chapter uses a moist static energy budget, which provides useful insight into the physical mechanisms that dominate intra-seasonal changes to precipitation.
- Chapter 7 investigates the tropical route of QBO teleconnections in the pre-industrial control experiments of HadGEM3 and UKESM1 and in targeted nudging experiments. The observational evidence that links the QBO with the ITCZ, ENSO and the Walker circulation is examined within these simulations to evaluate whether similar relationships to the observations are found within a state-of-the-art GCM. The results from these CMIP6 simulations are very similar to observations suggesting robust relationships between the QBO phase, the ITCZs and the Walker circulation. The

experiments with a nudged stratosphere improve the biases in the representation of the QBO, so their results can be used to test the causal pathway through which the tropical troposphere and stratosphere interact with each other. The results of this chapter show that when the relaxation was applied most of the teleconnections observed in the control experiments disappear, indicating either that the mechanisms that modulate stratospheric-tropospheric coupling were obscured by the experimental design or that the QBO variability is not driving these teleconnections.

2

Background

This chapter first summarises the main aspects and theoretical frameworks of the tropical circulation including the global monsoon. Then, the American Monsoon System is introduced and detail is given on the Midsummer drought of southern Mexico and Central America and El Niño Southern Oscillation teleconnections to this monsoon. Finally, a summary of the literature on tropical stratospheric-tropospheric coupling is given by describing the stratospheric quasi-biennial oscillation (QBO) and existing evidence linking the QBO to the tropical troposphere and monsoons.

2.1 The tropical circulation and the global monsoon

Tropical climate is a result of the strong solar insolation that year-round provides a stronger surface heating compared to extra-tropical latitudes. These latitudinal differences in solar insolation generate a meridional heat transport by the coupled atmosphere-ocean system. This means that the tropics have a positive annual net energy and the extra-tropics show an annual negative net energy balance. Tropical dynamics is also distinct from extra-tropical latitudes due to other physical features such as the relative extent and location of the continents, the Coriolis effect, and the characteristics of wave-propagation through the atmosphere. Generally, tropical dynamics is considered to be less well understood than mid-latitude dynamics, because most of the assumptions of mid-latitude dynamical frameworks

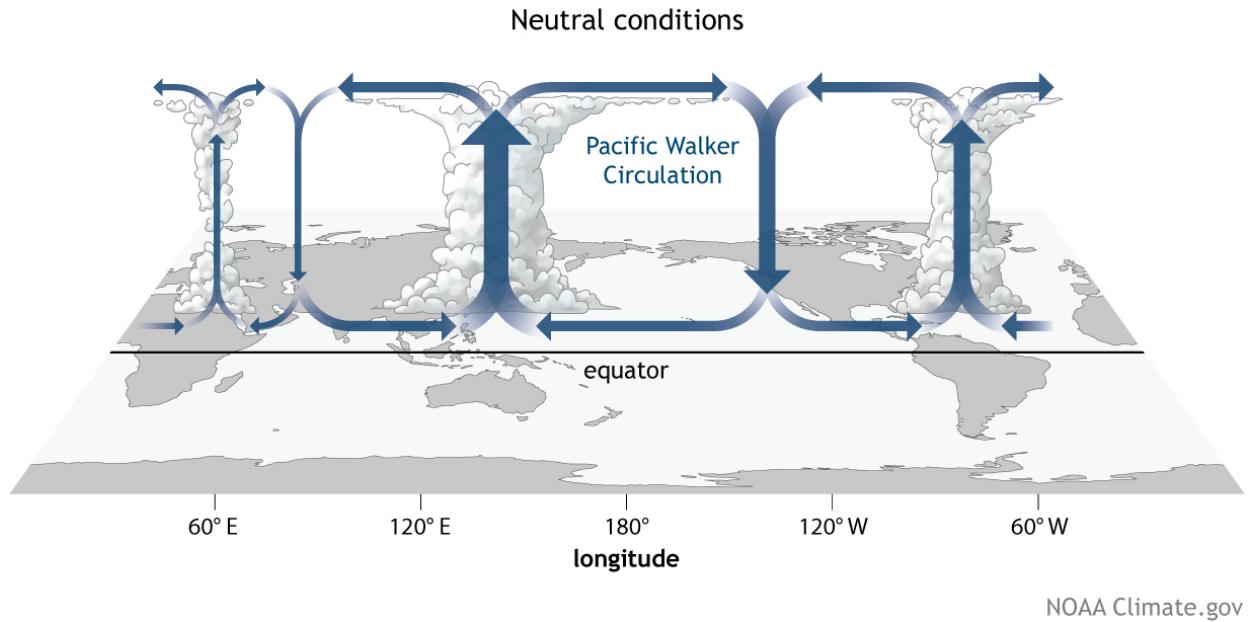

Figure 2.1: A schematic of the Walker circulation, depicting the mean zonal and vertical circulations, under neutral conditions of El Niño-Southern Oscillation. Schematic originally from: www.climate.gov/.

break down in the tropics, but also because reliable data in the tropics was scarce until satellite observations began in the 1980s (Emanuel, 2007; Webster, 2020).

Deep moist convection is one of the characteristic thermodynamic and dynamic traits of a tropical climate, which can modulate regional and large-scale circulation (Emanuel et al., 1994; Webster, 2020). Moist convective systems span different spatial and temporal scales, from short-lived cumulonimbus showers to tropical cyclones. Convective activity can generate large-scale propagating waves and cause long-distance impacts (Hartmann, 2015; Li and Hsu, 2018). The location and strength of deep convection in the tropics is intertwined with the large-scale tropical circulation, which is typically divided into meridional and zonal overturning circulations, the Hadley and Walker circulations.

The Hadley cell is the meridional overturning circulation that arises from the differential heating between the tropics and the midlatitudes. This overturning cell is characterized by ascending motions in the tropics and descending motions in the subtropics and acts to transport heat poleward from the equator (Lorenz, 1967). The ascending section of the Hadley circulation migrates meridionally with the seasonal cycle, the ascending and descending branches of the cell interact with each other but also with the midlatitudes

through eddy momentum fluxes (Bordoni and Schneider, 2008). The Hadley cell is not zonally symmetric; the boreal summer Hadley cell, for instance, is primarily a result of ascent in the Indian Ocean and the West Pacific regions with a minor contribution from ascending motions in Central and North America (Hoskins et al., 2020).

In turn, zonal circulations also exist in the tropical atmosphere and the most prominent example is the Walker circulation. The Walker circulation is the zonal overturning circulation that is found in the equatorial Pacific Ocean, illustrated in Figure 2.1 and characterized by ascending motion over the West Pacific and descending motions over the East Pacific (Walker, 1924; Bjerknes, 1969; Gill, 1980). The dynamic and thermodynamic effects of the location and strength of convection associated with the Walker circulation have strong impacts across the tropical and extra-tropical atmosphere (Cai et al., 2019).

Another prominent feature of the tropical climate is the Intertropical Convergence Zone (ITCZ), which is a coherent band of convective clouds and precipitation that migrates meridionally with the seasons, characterized by strong convergent flow at low levels and a strong divergent flow at upper levels which leads to a large positive vertical mass flux and ascent (Schneider et al., 2014; Byrne and Schneider, 2016). The ITCZ is collocated with the position of ascending branch of the Hadley cell (Donohoe et al., 2013; Hartmann, 2015). The strength of convection in the ITCZ is such that the largest precipitation rates in the tropics are typically found in the ITCZ.

The position and strength of the ITCZ results from the inter-hemispheric energy and momentum balances so that the ITCZ is predominantly found north of the equator because of the inter-hemispheric temperature contrast (Donohoe et al., 2013; Bischoff and Schneider, 2016; Byrne and Schneider, 2016). Over regional scales, the seasonal migration of the ITCZ follows closely the seasonal cycle of SSTs, which depends on the solar insolation and the coupling between SST gradients, cloud radiative heating and the low-level easterly flow (see e.g. Richter et al., 2014; Siongco et al., 2015; Oueslati and Bellon, 2015; Harrop and Hartmann, 2016). Variability in the characteristics of the ITCZ can affect relatively remote regions through impacts in the tropical convective heating, a modulation of the wave-train propagation and by modifying the strength and location of descending regions (Neelin and Su, 2005; Neelin, 2007; Cai et al., 2019).

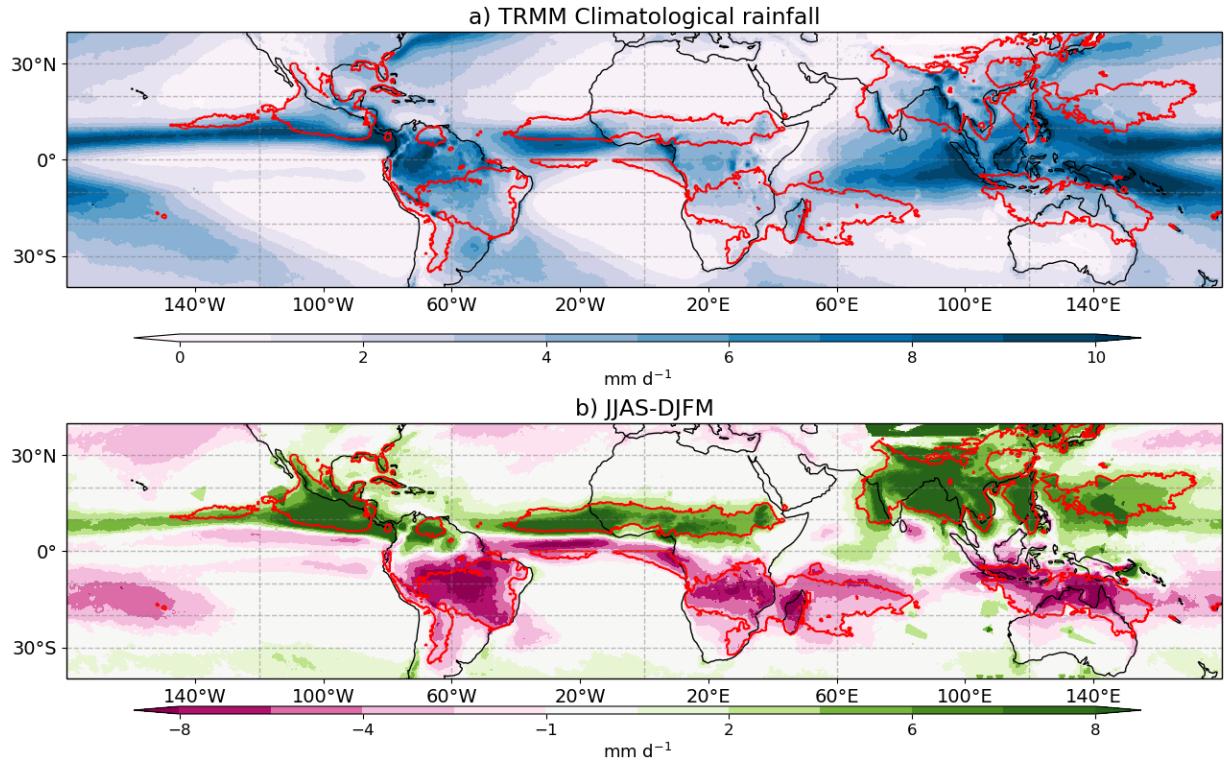

Figure 2.2: a) Climatological mean annual rainfall rates in the tropics using data from the Tropical Rainfall Measurement Mission (TRMM) dataset (1999-2018). b) The mean rainfall rate difference between boreal summer (JJAS) and austral summer (DJFM). The red contours highlight the regions where the mean summer rainfall amount accounts for more than 55% of the mean total annual rainfall accumulation.

In spite of the global impact of the ITCZ and tropical circulations, one of the phenomena of tropical climate that first generated research interest is the monsoon (Halley, 1687). The word *monsoon* stems from the Arabic word for *season* and this definition illustrates the very first conceptions of a monsoon. The first widely accepted view of a monsoon suggested that it was the result of a large-scale land-sea breeze associated with the differential warming of the land and the ocean that force a seasonal reversal of the low-level winds bringing seasonal rainfall to a region (Halley, 1687).

The traditional definition of the monsoon as a land-sea breeze has several shortcomings. Firstly, several mid-latitude regions would fit a monsoon definition based solely on a seasonal reversal of the wind (Gadgil, 2018), and secondly, regions that are now recognized as a region with a monsoon climate, e.g. in South America, do not show a seasonal reversal of the winds, and the wind flow may just exhibit seasonal changes in direction and strength

(Vera et al., 2006). For these reasons, the land-sea breeze view of monsoons has recently been replaced by three alternative conceptions, an ITCZ-monsoon framework, a convective quasi-equilibrium interpretation and a moist static energy (MSE) zonal-mean energetic interpretation (Biasutti et al., 2018; Hill, 2019; Geen et al., 2020).

The first framework explains monsoons as a poleward extension of the ITCZ into land generalizing all monsoons as an expression of global tropical convergence resulting from the energy balance (Chao and Chen, 2001; Gadgil, 2018). This interpretation has led to the concept of *the global monsoon*, a term that encompasses all the regions in the tropics that exhibit a strong seasonality in precipitation (Zhou et al., 2016; Gadgil, 2018). In practice, the global monsoon refers to those regions of the planet where more than 70% of the total annual rainfall is observed during the local summer season, therefore, the concept of a global monsoon recognises the seasonality of precipitation as the key feature to diagnose a monsoon (Zhou et al., 2016; Wang et al., 2017).

Figure 2.2 shows the global monsoon as depicted by the TRMM dataset. By this definition, the majority of the regions over land between 5 and 10 degrees away from the equator are part of the global monsoon. A regional monsoon, such as the Indian Monsoon, is then a subset of the global monsoon with unique regional characteristics that shape this monsoon differently to other regional monsoons in terms of the seasonality, the strength and the dynamics. The American Monsoon System is defined then as the regions of America that fit this definition.

Bordoni and Schneider (2008) provide an alternative conceptual view of monsoons, describing the characteristic rapid onset of a monsoon as a regime transition of the Hadley cell from an eddy momentum-driven circulation, which resembles a canonical ITCZ regime, to a thermally direct circulation which resembles a monsoon-like circulation. The zonal mean MSE meridional gradient drives the ITCZ location and determines the strength of the overturning circulation by modulating the ventilation from the midlatitudes that bring cooler and drier air in a feedback mechanism (Geen et al., 2020). Even though Bordoni and Schneider (2008) propose an axisymmetric framework, their predictions were broadly consistent with the Asian monsoon circulation.

Another conceptual view of monsoon uses Convective quasi-equilibrium (CQE), which is a theory for moist convection where convection sets the vertical temperature and moisture

profiles to a convectively neutral state, thereby setting the free tropospheric temperature (Neelin, 2007). For a monsoonal circulation, this theory emphasizes the coupling of convection and dynamics predicting that the sub-cloud layer equivalent potential temperature maxima must be collocated with the free tropospheric saturation equivalent potential temperature (Nie et al., 2010; Geen et al., 2020). The rapid onset of the Asian monsoon is associated with the boundary layer moist entropy distribution, in agreement with predictions of CQE (Nie et al., 2010; Boos, 2015; Ma et al., 2019).

Several studies examine the monsoon as a large-scale phenomenon through an axisymmetric framework that assumes zonal symmetry investigated through global energetic diagnostics (e.g. Faulk et al., 2017; Geen et al., 2019; Byrne and Zanna, 2020). The zonal-mean framework is common to the Hadley cell interpretation of monsoons (Bordoni and Schneider, 2008), as well as the ITCZ-monsoon theory. However, regional monsoons are shaped by the asymmetries imposed by the orography, the characteristics of the surrounding ocean basins, land-sea contrasts and also the role of vegetation-hydrology coupling (Wang et al., 2017; Pascale et al., 2019). The importance of zonal asymmetries has raised multiple issues with theories of large-scale monsoon dynamics, as several predictions of these theories are not consistent with observations of regional monsoons (e.g. Nie et al., 2010; Smyth et al., 2018; Biasutti et al., 2018; Pascale et al., 2019).

The MSE budget framework suffers both from theoretical and practical shortcomings. One practical shortcoming is that the calculation of the budget terms post hoc in reanalysis or models results in very large residuals (Hill, 2019), so these frameworks work best when the calculations of the budget terms are integrated online at each time-step (e.g. Ma et al., 2019). Another shortcoming is that the surface fluxes over land, e.g., in the Sonoran and Saharan deserts and the deep Amazon make the estimations of the roles of hydrology-vegetation feedbacks and their potential contributions to the MSE budget in observations very difficult to assess (Boos and Korty, 2016; Pascale et al., 2019). The use of simpler moisture budgets has proven useful in a regional context to investigate the sources of moisture for monsoons in current (Ordoñez et al., 2019; Martinez et al., 2019) and future climates (Smyth and Ming, 2020), and in any case the MSE budget is a tool and not a coherent theory for the dynamics of monsoons.

The Hadley cell interpretation of monsoons has significant shortcomings to depict some regional monsoons, particularly those that are not the Asian monsoon as the overturning circulation in the South Asian monsoon is strong enough to be represented by a clear thermally direct regime. However, this energetic framework assumes no zonal transport of energy, which minimizes the role of orography and land-sea interaction (Biasutti et al., 2018), which may explain why the North American monsoon does not exhibit the circulation described by Bordoni and Schneider (2008). One might reasonably infer from these results that the timing of the transition in the zonal mean overturning cells would be similar for monsoons at different longitudes but similar latitudes, which is not the case (Wang et al., 2017).

Recent reviews acknowledge that all these frameworks have significant shortcomings when applied to regional monsoons (Biasutti et al., 2018; Hill, 2019; Geen et al., 2020). These reviews conclude that a framework that reconciles the global energetic perspective with the characteristics of regional monsoons would be crucially important and very useful, but also very hard to formulate. **In summary, there is no detailed physical description of the global monsoon system with a single theoretical formulation that can explain the observed features of all the regional monsoons.**

Furthermore, a monsoon restricted to a small area, such as the North American and African monsoons may not show a clear zonally averaged overturning regime and may be significantly affected by local shallow and deep circulations (Zhai and Boos, 2015). For instance, Smyth et al. (2018) show that the simulated West African monsoon when forced with different solar forcings exhibits a decoupling between the zonal-mean ITCZ location, the strength of the local Hadley cell and the monsoon rainfall, in opposition to the predictions of this framework (Bordoni and Schneider, 2008).

In short, despite significant progress in our understanding of the monsoon phenomena at the planetary scale through zonal mean energetic frameworks, there is an important gap between large-scale theories of monsoon dynamics and the observed regional monsoons. The next section presents a summary of the North and South American monsoon literature, which explains the characteristics of these monsoons through the effect of regional features and dynamics, seemingly detached from the literature in this section.

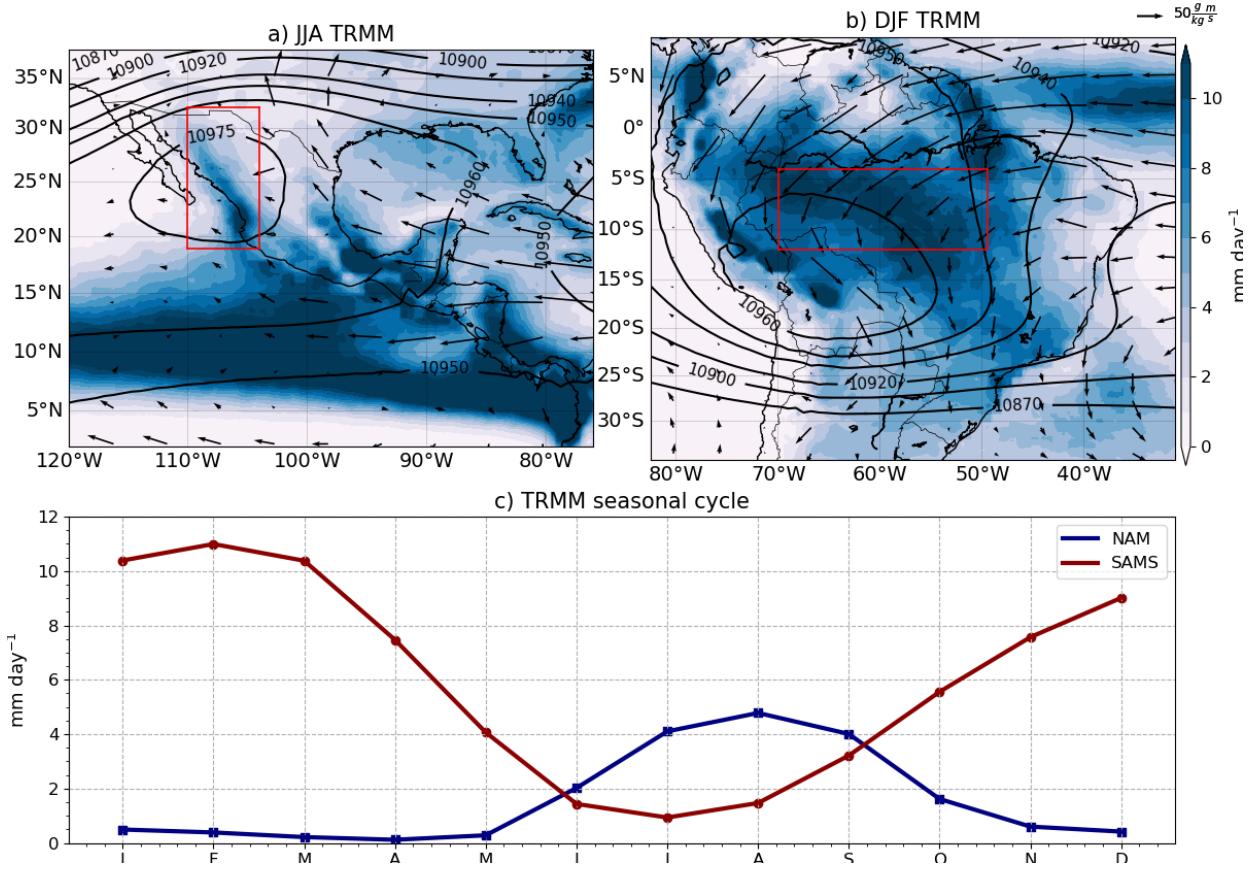

Figure 2.3: Climatological mean a) boreal and b) austral summer rainfall (shading), 850 hPa moisture flux (vectors) and geopotential height at 250 hPa (contours) in a) southern North America and b) South America. c) Monthly-mean seasonal march of precipitation in the TRMM dataset for two area-averaged time-series, the North American Monsoon (NAM) and the South American Monsoon System (SAMS) shown in the red rectangles in a-b).

2.2 The American Monsoon System

The American Monsoon System (AMS) is the main source of rainfall for tropical Latin America and is typically subdivided into the North and South American monsoon systems (Vera et al., 2006). Although the spatial definition of the AMS is quite varied amongst studies, a general consensus is that the North American Monsoon is found in south-western North America (Figure 2.3a) extending north from central-west Mexico into the southwestern United States and the South American Monsoon is centred in the deep Amazon south to the river mouth (Figure 2.3b) but southeastern Brazil (Adams and Comrie, 1997; Stensrud et al., 1997; Vera et al., 2006).

The seasonal cycle of rainfall in the North American Monsoon is characterised by a wet

July-August-September season and significantly drier conditions during the rest of the year (Adams and Comrie, 1997) (Figure 2.3c). Three temporal stages describe the evolution of the North American Monsoon (Adams and Comrie, 1997; Geil et al., 2013). First, the onset stage (May-June) starts with a strong surface warming that leads to very high temperatures in the desert region. Simultaneously, the subtropical jet weakens and migrates north decreasing the frequency of mid-latitude disturbances in the monsoon region (Douglas et al., 1993; Turrent and Cavazos, 2009). These factors combine to develop a low-level thermal surface low pressure linked with an upper-level anticyclone and moisture influx from the nearby Gulf of California and easternmost Pacific Ocean (Douglas et al., 1993; Geil et al., 2013).

Maturity (July-August) is the peak period of monsoon rainfall characterised by sustained deep convection (Barlow et al., 1998) and significant increases in low and mid-level moisture flux convergence and mid-level latent heating (Adams and Comrie, 1997; Cook and Seager, 2013). The latent heating caused by deep convection can be diagnosed in the upper-level geopotential height (Figure 2.3a) in the form of an anticyclone centred on the monsoon region. The moisture flux convergence decreases in August, after which precipitation recycling (Dominguez et al., 2008) plays an important role in keeping deep convection active until September. Decay (September-October) is the last stage of the monsoon, in many ways opposite to the onset stage, as is characterised by the equatorward migration of the subtropical jet (Higgins et al., 1997; Geil et al., 2013), evaporation in the nearby basins decreases and deep convection in the monsoon region disappears (Douglas et al., 1993).

The origin of moisture at low and mid-levels in the monsoon region has been a matter of debate (Adams and Comrie, 1997; Barlow et al., 1998; Vera et al., 2006; Ordoñez et al., 2019), but evidence suggests that the main source of moisture is the East Pacific Ocean and, to second order, mid-level moisture advected from the Gulf of California (e.g. Adams and Comrie, 1997; Stensrud et al., 1997; Vera et al., 2006; Turrent and Cavazos, 2009; Ordoñez et al., 2019). However, a more puzzling aspect is how exactly is moisture advected and organized specifically on the western coast of northern Mexico. Orography seems to be the dominant fact as the Sierra Madre Occidental (SMO) found in the core NAMS region is a key feature of this monsoon.

Early studies suggest that the role of the SMO is to channel moisture from the East Pacific and Gulf of California (Seastrand et al., 2015) or in a mountain-sea breeze mechanism operating with the diurnal cycle of the low-level winds (Nesbitt et al., 2008). However, Boos and Pascale (2021) provide an alternative hypothesis for the role of the SMO in the organization of the monsoon in southwestern North America. Their results suggest that the role of the SMO is to deflect the subtropical jet and produce an eastward upward flow that organizes convection in a confined region with relative high surface moist static energy.

The South American Monsoon System (SAMS) is a primary source of precipitation for South America, especially in the Amazon region (Gan et al., 2004; Vera et al., 2006; Jones and Carvalho, 2013). During austral summer (DJF), monsoon rainfall accounts for over 60% of the total annual precipitation in the Amazon (Gan et al., 2004; Marengo et al., 2012), whereas austral winter rainfall accounts for less than 5% of the total annual rainfall (Vera et al., 2006).

In the central Amazon, convective precipitation is observed from early October but the main rainy season extends from December to April (Machado et al., 2004; Adams et al., 2013), whereas convection in southeastern Brazil and Paraguay starts in November and peaks in January and February (Marengo et al., 2001; Nieto-Ferreira and Rickenbach, 2011). A surface heat low appears in Bolivia in early austral summer, known as El Chaco Low, as a result of strong warming in austral spring (Marengo et al., 2012; Sulca et al., 2018). Simultaneously, an upper-level anti-cyclone (Fig. 2.3b), known as the Bolivian High, develops in the same region as a signature of strong deep convection and latent heating (Marengo et al., 2001; Vera et al., 2006).

The South American Low-Level Jet (SALLJ) and the South Atlantic Convergence Zone (SACZ) are two primary climatic features of the SAMS (Vera et al., 2006; Marengo et al., 2012; Jones, 2019). The SACZ is observed as a northwest-southeast oriented band of convection (Carvalho et al., 2004; Nobre et al., 2012; Jorgetti et al., 2014; Zilli et al., 2019) that is more frequently active during austral summer in association with the onset of the SAMS (Marengo et al., 2012; Perez et al., 2021).

The coherent band of organized convection in the SACZ forms from the convergence of moisture emanating from the South Atlantic Subtropical High and from the northerly flow from the Amazon (Marengo et al., 2012; Zilli et al., 2019). Moreover, mid-latitude

disturbances or wave-trains are key for the establishment and variability of the SACZ (Carvalho et al., 2004; Nieto Ferreira and Chao, 2013; Van Der Wiel et al., 2015; Zilli and Hart, 2021). Variability of the SACZ diagnosed as shifts to the position and strength of the band of convection are intertwined with the continental-scale moisture transport and precipitation in south eastern Brazil and central South America (Mo and Paegle, 2001; Jorgetti et al., 2014; Perez et al., 2021).

The low-level wind circulation imports moisture from the Atlantic Ocean. Once the flow has crossed through the Amazon, the low-level winds are steered by the Andes cordillera into the SALLJ (Geen et al., 2019; Jones, 2019). The variability of the SALLJ can modulate active and break phases of the monsoon as well as active days of the SACZ, through the modulation of the moisture transport across the continent (e.g. Liebmann and Mechoso, 2011; Grimm, 2011; Jones, 2019). In short, the SACZ and the SALLJ are prominent features of the mean SAMS but their variability also modulates the SAMS precipitation on multiple temporal timescales (e.g. Marengo et al., 2012; Junquas et al., 2012; Perez et al., 2021).

South American orography, which features the Andes cordillera, has long been investigated for its role in the dynamics of the SAMS (e.g. Rodwell and Hoskins, 2001; Campetella and Vera, 2002; Insel et al., 2010; Saurral et al., 2015; Junquas et al., 2016). Evidence shows that the Andes cordillera deflects the low-level wind flow from the equatorial Atlantic southward mechanically forcing the SALLJ (Campetella and Vera, 2002; Insel et al., 2010) and thereby contributing to the tropical-to-subtropical moisture transport. The Andes cordillera also blocks the westerly winds from the Pacific Ocean which would ventilate low-level moisture in South America (Insel et al., 2010) and the existence of the cordillera is key to the formation and location of the SACZ (Junquas et al., 2016).

The global monsoon theories discussed in the previous section struggle to accurately depict several aspects of the NAMS and the SAMS. For example, the North and South American Monsoons depart from CQE, as precipitation does not follow the maxima in sub-cloud equivalent potential temperature (Nie et al., 2010; Geen et al., 2020). The role of orography and soil-atmosphere interactions may be playing a big part in both the SMO and the Amazon to decouple the sub-cloud MSE and the free troposphere (see e.g. Boos and Pascale, 2021). One alternative hypothesis is that ventilation of low moist entropy air

from the midlatitudes is responsible for this decoupling of the boundary layer and the free troposphere in the American monsoons (Boos, 2015). Similarly, the meridional circulations associated with these monsoons do not fit the framework of Bordoni and Schneider (2008), which suggests an alignment of the maximum ascent with the maximum surface MSE, which is not observed in either monsoon of the AMS. As such, existing monsoon theories either do not fit the observed AMS, or need to be tailored to explain only one of these monsoons.

2.3 A review of the physical mechanisms for the Midsummer drought

The characteristics of the seasonal cycle of precipitation in northwestern Central America, the Caribbean and southern Mexico fit the definition of a monsoon climate (Wang et al., 2017) with a clear separation of the wet and dry seasons. However, this region shows a unique climatological precipitation feature. After monsoon onset, rainfall decreases considerably around midsummer; this decrease is followed by a secondary increase in precipitation in the late summer (Mosiño and García, 1966), and for this reason this feature of the seasonal cycle is most commonly referred to in the literature as the Midsummer drought (MSD) (Magaña et al., 1999). Although the MSD regions sometimes features in AMS studies (see e.g. Pascale et al., 2019), and is technically part of North America by some definitions, this region is not considered to be part of the North American monsoon.

The intraseasonal variations of precipitation associated with the MSD have been known for centuries and have shaped agricultural practices in the region. For example, ancient Mayan texts suggest that agricultural rituals associated with the plea for rain-bearing clouds to the gods were significantly more frequent during the drier MSD period (Jobbová et al., 2018). In current days, the MSD is well known by local farmers who refer to the drier midsummer period as ‘El Veranillo’ in Central America and ‘canícula’ in southern Mexico because the drier period coincides with the Canis Major constellation appearing in the sky (Dilley, 1996).

The two peak structure of the MSD has been diagnosed in the observed climatological precipitation of several regions of Mexico, El Salvador, Belize, Guatemala, Costa Rica and Cuba (e.g. Mosiño and García, 1966; Magaña et al., 1999; Durán-Quesada et al., 2017;

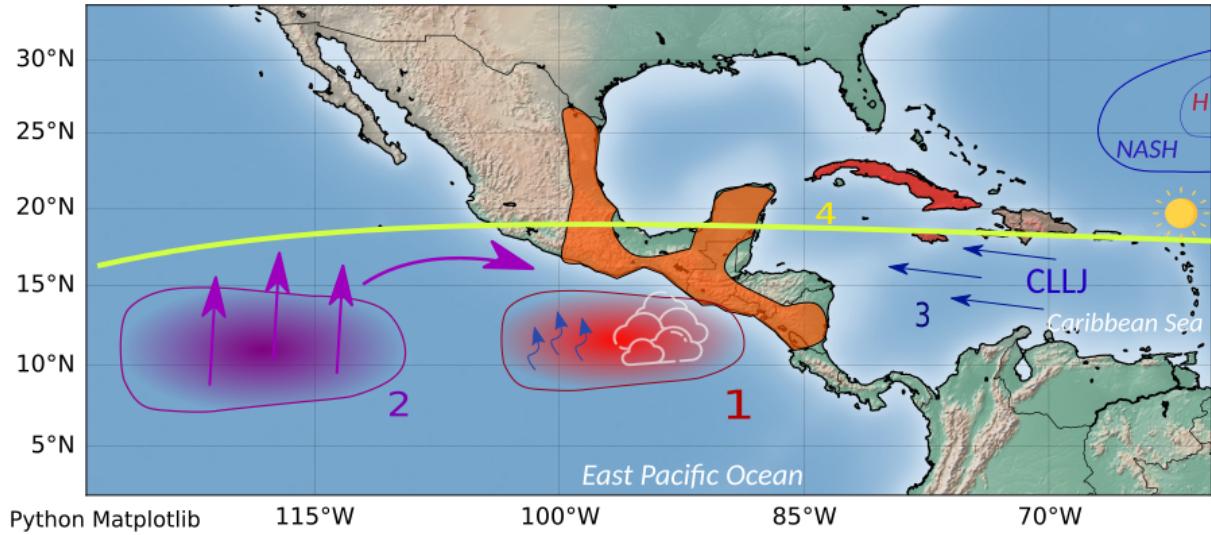

Figure 2.4: A schematic of the Intra Americas Seas region, depicting the four main mechanisms associated with the Midsummer drought in Mesoamerica (orange) and the Caribbean region (red). (1) The radiative-convective feedback mechanism associated with a double peak in East Pacific SSTs proposed by Magaña et al. (1999). (2) The ascending region west of the continent produces an anomalous descending motion over the continent through a direct circulation, argues Herrera et al. (2015). (3) The Caribbean Low-Level Jet (CLLJ) modulates the moisture transport for all the region, with several studies supporting the hypothesis that seasonal cycle in the CLLJ is the main mechanism for seasonal fluctuations in rainfall (Durán-Quesada et al., 2017; Martinez et al., 2019). (4) The double-crossing of the solar declination angle, proposed by Karnauskas et al. (2013), suggests that each peak of precipitation is associated with peaks in the total shortwave radiation reaching the surface. Note that the Mesoamerican MSD is not part of the North American monsoon (Adams and Comrie, 1997).

Perdigón-Morales et al., 2018; Martinez et al., 2019). However, notable differences in the seasonal cycle of precipitation have been found between mainland Central America and the Caribbean islands. The so-called first peak of precipitation occurs in June and the second peak in September in northern Central America whereas the two peaks are observed in May and October in the Caribbean.

Despite extensive research to understand the physical mechanisms associated with the MSD (e.g. Magaña et al., 1999; Giannini et al., 2000; Gamble et al., 2008; Herrera et al., 2015; Maldonado et al., 2017; Straffon et al., 2019), debate remains over which is the leading-order mechanism that causes rainfall to decrease at midsummer and increase again at the end of the summer. Fundamental questions remain unclear such as whether the MSD is caused by two precipitation enhancing mechanisms (Karnauskas et al., 2013) or a mechanism that inhibits

rainfall at midsummer (Durán-Quesada et al., 2017). Furthermore, the association between the MSD in Central America and the Caribbean is still disputed (Gamble et al., 2008), as most studies suggest that the two regimes are unrelated and therefore two different explanations are required to account for the two MSDs in these regions. Figure 2.4 summarises the four main mechanisms that will be addressed in this section and this thesis.

One of the first hypotheses to account for the bi-modal distribution of rainfall was proposed by Hastenrath (1967) who argue that a double-crossing of the ITCZ can explain the MSD so that the first peak of precipitation is associated with early summer northward crossing of the ITCZ and the second peak the return or southward displacement of the ITCZ during late summer. However, this theory fails to explain the MSD signal seen at latitudes as high as 29°N (Perdigón-Morales et al., 2018; Zhao et al., 2020), which is further north than the northernmost extension of the ITCZ (Schneider et al., 2014), and the ITCZ does not cross twice so far from the equator.

Magaña et al. (1999) and Magaña and Caetano (2005) proposed a mechanism driven by radiative-convective feedbacks between the East Pacific (EP) sea-surface temperatures (SSTs) and deep tropical convective clouds (mechanism 1 in Figure 2.4). The coupling between the height and strength of convection, the incoming shortwave radiation and the SSTs are the key features of their framework. The EP SSTs peak in May triggering large evaporative fluxes and deep convection in the EP ITCZ and the western coast of Central America. The high convective clouds produce a radiative cooling effect at the surface due to a decreased incoming shortwave radiation associated with the reflectance of shortwave radiation by clouds. This cooling decreases SSTs and deep convective activity and thus accounts for the decrease of rainfall during midsummer. The second peak in September is driven by an opposite mechanism, i.e., the decreased frequency of deep convective clouds during the MSD period in July and August reduces the cooling effect of the anvil clouds and increase the incoming shortwave radiation at the surface, SSTs and surface fluxes, all of which leads to an increase in precipitation during late August and September (Magaña et al., 1999).

A large number of studies, in contrast, propose that the seasonal evolution of the North Atlantic Subtropical High (NASH) is the leading mechanism for the MSD (e.g. Mapes et al., 2005; Small et al., 2007; Gamble et al., 2008; Curtis and Gamble, 2008; Muñoz et al.,

2008; Martinez et al., 2019; Corrales-Suastegui et al., 2020). The NASH is the subtropical anticyclone in the North Atlantic Ocean that migrates southwest during early boreal summer. The expansion and intensification of the NASH in boreal summer, according to these studies, strengthens the low-level trade winds, controlling the seasonal cycle of a low-level jet found in the core of the Caribbean Sea known as the Caribbean Low-Level Jet (CLLJ).

The CLLJ is a key regional feature of the climate of the Caribbean and the Intra-Americas Sea because the strength and direction of the flow in the Caribbean controls the underlying Caribbean SSTs and the regional moisture transport (Giannini et al., 2000; Mestas-Nuñez et al., 2007; Martinez et al., 2019; García-Martínez and Bollasina, 2020). However, studies disagree on the specific roles that the CLLJ and the NASH play to modulate seasonal cycle of precipitation over the Mesoamerican region. For example, some studies (e.g. Giannini et al., 2000; Mestas-Nuñez et al., 2007; Gamble et al., 2008) suggest that the expansion of the western flank of the NASH strengthens the CLLJ which cools the SSTs, through the effect of wind stress and mixed-layer mixing. The cooling of SSTs diminishes evaporation and therefore low-level moisture which ultimately leads to less precipitation. In contrast, other studies propose that the seasonal cycle of the CLLJ (mechanism 3 in Figure 2.4) modulates seasonal variations of precipitation by modulating the regional moisture transport (Small et al., 2007; Muñoz et al., 2008; Herrera et al., 2015; Durán-Quesada et al., 2017; Martinez et al., 2019). In this second hypothesis, the changes to the intensity of CLLJ influenced by the NASH modify the convergence and divergence patterns in the Intra-Americas Sea. In other words, the midsummer strengthening of the CLLJ increases moisture divergence, drying the atmospheric column over the Caribbean.

Herrera et al. (2015) show that during the drier months in Central America in the Midsummer, convective activity west of the central American continent gets stronger with heavier precipitation (mechanism 2 in Figure 2.4). Their evidence suggests that the gap flow that originated from the CLLJ in the Caribbean Sea controls the location of ascending and descending motions, and the MSD may be explained by the seasonal variations of the coupling of the low-level wind flow with the underlying EP SSTs. Herrera et al. (2015) further argued that the exit region of the CLLJ is located to the east of the region of the strongest MSD signal, which suggests that the moisture divergence effect over the central American MSD is minimal.

A different mechanism, proposed by Karnauskas et al. (2013), argues that the biannual crossing of the solar declination angle can control precipitation and explains the bimodal characteristics of the seasonal cycle (mechanism 4 in Figure 2.4). In this mechanism, the MSD is driven by two precipitation enhancing periods that are separated by a relatively normal, and drier, period. This theory differs from those previously discussed which explained the MSD through mechanisms that inhibit convective activity in the midsummer whereas Karnauskas et al. (2013) argues that the solar declination angle that crosses twice through Central America, once during June and a second time during September, increases convective activity during each crossing.

The variations of incoming shortwave radiation associated with the declination angle modulate the SSTs, surface fluxes and therefore convective activity. In other words, the first crossing of the solar declination angle increases the incoming shortwave radiation which increases the SSTs, evaporation and leads to a peak of precipitation, i.e., the first peak. After the shortwave radiation is reduced the MSD period appears. The second crossing of the solar declination angle, similarly, explains the second peak as the second increase in incoming shortwave radiation drives an increase in deep convection.

Other mechanisms have been proposed arguing that the MSD is a result of vertical wind shear affecting convective instability or the Saharan dust controlling the microphysics of clouds (Angeles et al., 2010). For instance, Perdigón-Morales et al. (2019) also finds a link between the frequency and spatial distribution of the first peak rainfall rates and the Madden-Julian Oscillation (MJO). In short, a plethora of hypotheses exist for the causes of the seasonality of the MSD, however, a key aspect of the climate of the AMS is the effect of ENSO, which is described and discussed in the following section.

2.4 El Niño Southern Oscillation: impacts on the American monsoon system

El Niño-Southern Oscillation (ENSO) is a coupled ocean-atmosphere phenomena in the equatorial Pacific Ocean that is profoundly important for the global climate system, which is why ENSO is commonly known as the leading mode of interannual variability. The term '*El*

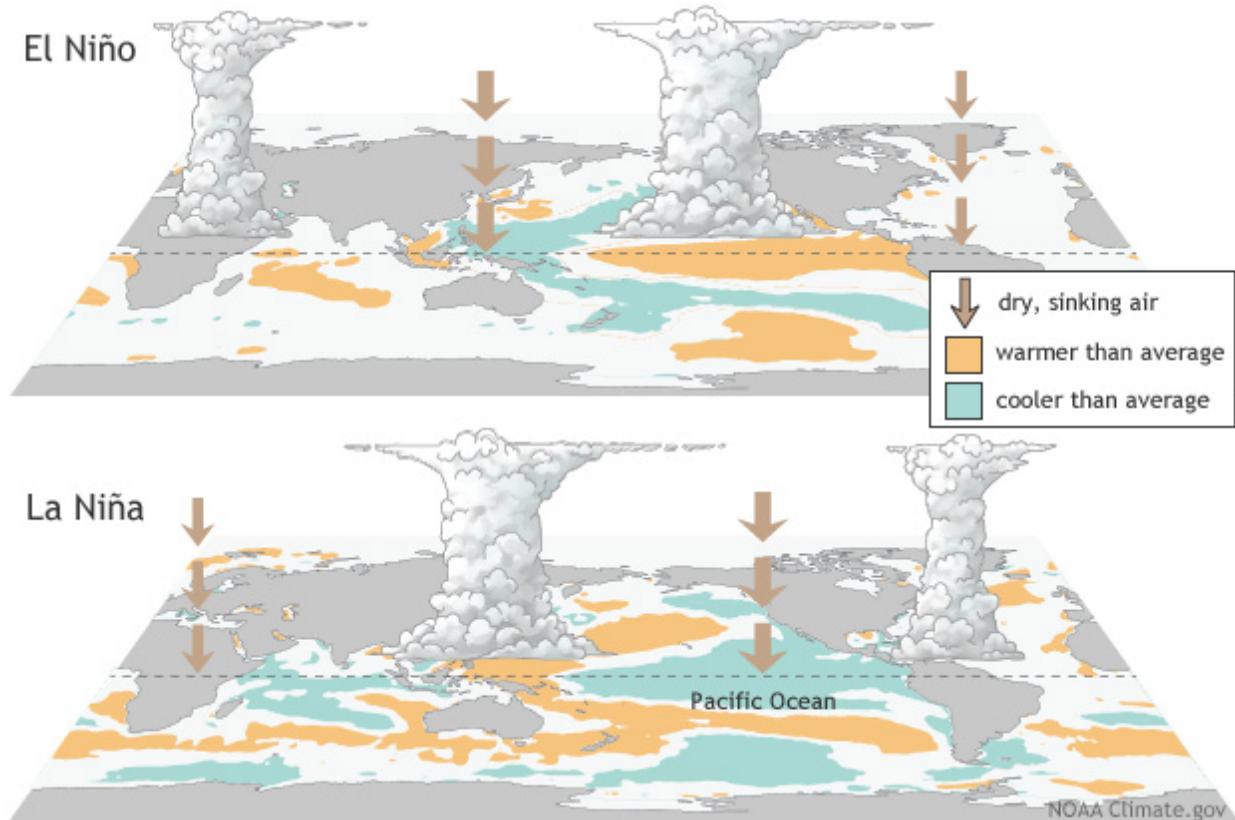

Figure 2.5: Schematic of the positive (upper) and negative (lower) phases of ENSO. Regions with tall clouds indicate more ascent and convection than normal whereas brown arrows indicate dry descending air. Obtained from the National Oceanic and Atmospheric Administration at <https://www.climate.gov/enso>.

Niño' was coined by Spanish colonizers when they learnt from Peruvian fishermen that the SSTs in the easternmost Pacific Ocean increased notably in some years around December time. Later on, sir Gilbert Walker (1924) coined the term *Southern Oscillation* to describe the synchronous changes to the sea-level pressure of the Indo-Pacific region and South America. ENSO is then characterized as a coupled phenomenon composed of an oceanic part, *El Niño*, and an atmospheric component associated with the zonal circulation but best characterized by changes to the surface pressure field, i.e., the Southern Oscillation.

ENSO has several unique features, such as no robust periodicity as events may occur every 2 to 7 years and a seasonal phase-locking that are associated with ENSO events peaking in boreal winter in observations (Wang and Picaut, 2004). Even though the underlying physics that cause ENSO and explain the variability in the periodicity of the phenomena is still debated (Wang and Picaut, 2004; Christensen et al., 2017), several aspects are now better

understood. For example, the impact of ENSO events on the location and strength of deep convection in the equatorial Pacific have been thoroughly described and the teleconnections pathways of ENSO are well characterized (Trenberth, 1997; Neelin et al., 1998).

During a neutral state of ENSO, the Walker circulation is found in the climatological state, with ascent and wet conditions in the West Pacific and descent and drier conditions in the East Pacific. During El Niño the Walker circulation and low-level trade winds weaken which is associated with an eastward shift of deep convection along the equatorial Pacific (Figure 2.5), with convective rainfall becoming more frequent in the central and even eastern Pacific than normal (Neelin et al., 1998; Wang and Picaut, 2004). During La Niña the opposite happens and the Walker circulation strengthens which leads to stronger convection in the West Pacific and stronger ascent on the East Pacific (Figure 2.5).

In other words, ENSO imposes a strong control on the location and strength of the Walker circulation (Figure 2.5). These changes to the strength and position of the convective regions in the Pacific Ocean can then propagate to other regions of the planet; these far-distant effects are commonly known as *teleconnections*. ENSO teleconnections work through various pathways or mechanisms which include extra-tropical routes such as changes to the position and strength of subtropical jets (Fereday et al., 2020), to the Pacific and North American circulation patterns (Bayr et al., 2019) as well as impacts to the North Atlantic via the stratospheric polar vortex (Domeisen et al., 2019).

ENSO teleconnections impact the AMS regions through both tropical and extratropical pathways (Marengo et al., 2012; Sulca et al., 2018; Cai et al., 2020). For example, Figure 2.5 shows the impact of ENSO over other tropical regions outside of the Pacific through the Walker circulation, as upper-level wind anomalies induce anomalous vertical motions over West Africa (Ropelewski and Halpert, 1986, 1987) or South America (Sulca et al., 2018). The extratropical pathway involves anomalous Rossby wave-trains caused by tropical convective heating that propagate from the equatorial Pacific to the extratropical Pacific and Atlantic affecting both northern and southern hemispheres (Hoskins and Karoly, 1981; Jiménez-Esteve and Domeisen, 2018; Fereday et al., 2020). These wave-driven anomalies cause differences in the regional sea-level pressure systems and the location of the storm track.

For example, ENSO induces changes to the Aleutian Low pressure system and similar SLP anomalies of opposite sign over the North American continent, in a teleconnection pattern that is more commonly referred to as the Pacific-North American (PNA) and which also influences the underlying SSTs (Deser et al., 2010; Lin, 2015; Bayr et al., 2019; Jiménez-Esteve and Domeisen, 2020). A similar teleconnection is observed as wave trains travelling from the South Pacific to the South Atlantic, i.e., the Pacific-South American (PSA) pattern (Mo and Paegle, 2001; Vera and Silvestri, 2009; Cai et al., 2020). Specifically, El Niño events induce a positive phase of the PNA pattern during boreal winter which leads to enhanced precipitation and colder conditions over northern Mexico due to the increased frequency of the intrusion of cold mid-latitude disturbances (Magaña et al., 2003).

The tropical pathway involves the changes to the location and strength of the Walker circulation explained above, in which anomalous descending and ascending anomalies are found in the Amazon region for El Niño and La Niña years, respectively. Another impact in the North Atlantic is indirectly caused by via the modulation of the PNA pattern on the easterly trade winds in the subtropical Atlantic which subsequently impacts the Atlantic ITCZ (Hastenrath, 2006; Fereday et al., 2020). For instance, El Niño teleconnections through the PNA pattern lead to a warming of the northern tropical Atlantic SSTs which induce a delay in the seasonal migration southwards of the Atlantic ITCZ causing a drying of northern South America (Hastenrath, 2006; Cai et al., 2020). The influence of the northern tropical Atlantic and the delay in the southward shift of the Atlantic ITCZ not only influences rainfall over northeastern Brazil but also modulates extreme events throughout the SAMS (Yoon and Zeng, 2010; Andreoli et al., 2012; Jimenez et al., 2021).

Current research on ENSO teleconnections to South America focuses on the observed non-linearity and asymmetry of the impacts, which has mainly been attributed to ENSO diversity (Tedeschi et al., 2015; Cai et al., 2020; Jimenez et al., 2021). ENSO diversity refers to the observed feature that the maximum SST anomaly does not always appear in the same region of the Pacific Ocean (Ashok and Yamagata, 2009; Dommenech et al., 2013). These differences in the SST patterns are referred to as ENSO *flavours* which can be broadly summarized as two flavours for each phase. The flavours are defined based on the location of the SST anomaly so the most common division is into Central and

Eastern Pacific events. In observations, each type of event is usually also associated with the strength of the event (Dommegget et al., 2013), with eastern Pacific events being usually stronger than Central Pacific events.

ENSO diversity has important implications for global teleconnections; specifically, precipitation impacts and the occurrence of droughts in the SAMS have been linked to non-linear effects associated with the location of the SST anomalies in the Pacific (Rodrigues et al., 2011; Sulca et al., 2018; Cai et al., 2020; Jimenez et al., 2021). Cai et al. (2020) provides a recent review on the differences in the impacts that Central and Eastern Pacific (CP and EP) events have on South American precipitation and climate features. The observed record shows that the teleconnections affecting the Amazon and northeastern Brazil are most pronounced during EP El Niño events and CP La Niña events than the CP El Niño events and EP La Niña events.

Cai et al. (2020) also highlights the need for further modelling work to test observation-driven hypothesis, as the observed record is too short to make confident statements about the mechanisms associated with non-linear ENSO teleconnections. Specifically, there are still open questions regarding the effect of other climate variability factors on the teleconnections, particularly for different ENSO flavours, and the role of other ocean basins such as the Indian and Atlantic Oceans in the modulation of ENSO effects (Cai et al., 2019).

2.5 The QBO and tropical convection

2.5.1 The Quasi-biennial oscillation (QBO)

The stratospheric quasi-biennial oscillation (QBO) was discovered 60 years ago through balloon observations that revealed that, in the tropical stratosphere (from 10-20 km up to 50 km in altitude (Andrews et al., 1987)), the zonal winds reverse direction in a semi-periodic way with accompanying temperature variations (Ebdon, 1960; Reed, 1964). Since the QBO was discovered, further observations have described it as alternating easterly and westerly wind regimes associated with a descending zonal wind shear with a mean oscillatory period of 28 months (Baldwin et al., 2001). The downward propagation of the easterly and westerly wind regimes, amplitude and the mean period have been explained by the interaction of

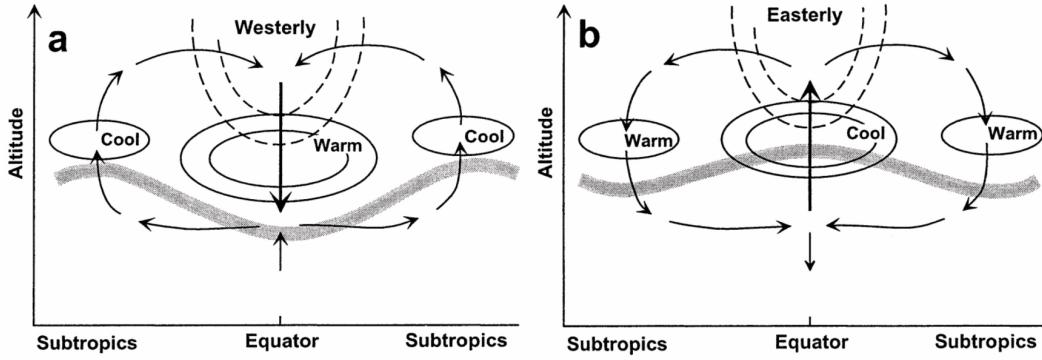

Figure 2.6: Schematic diagram from Collimore et al. (2003) of the QBO mean meridional circulation for regimes classified as descending (a) QBOW and (b) QBOE. The diagram shows temperature (solid contours) and zonal wind (dashed contours) anomalies as well as tropopause altitude (gray lines).

a broad spectrum of gravity and Kelvin waves of tropospheric origin with the equatorial stratospheric zonal mean flow (Baldwin et al., 2001).

The wind variation in the middle stratosphere associated with the QBO are greater than the seasonal cycle (Andrews et al., 1987) and this vertical wind shear imposes a temperature signal through the thermal wind relationship, which can be expressed as:

$$\frac{\partial u}{\partial z} = \frac{-R}{H\beta} \frac{\partial^2 T}{\partial y^2}, \quad (2.1)$$

where $\partial u / \partial z$ is the vertical shear of the zonal wind, R is the ideal gas constant, y is the latitude, H is a scale height of the atmosphere (7–8 km) and β is the first derivative of the Coriolis term in the meridional coordinate y .

In order to maintain thermal wind a westerly (easterly) vertical shear requires a latitudinal temperature gradient with a warm (cold) temperature anomaly over the equator. These temperature anomalies are achieved through an induced mean meridional circulation (Figure 2.6), often referred to as the secondary circulation of the QBO (Plumb and Bell, 1982; Li et al., 1995; Baldwin et al., 2001; Ribera et al., 2004). This anomalous circulation is characterized by reduced upwelling during westerly shear phases and increased upwelling during the easterly phase. These meridional circulation perturbations adiabatically warm (anomalous descent at the equator) and cool (anomalous ascent) for westerly and easterly shears, respectively, at the equator (Fig. 2.6).

These induced meridional circulations also give rise to an ozone anomaly, with positive (negative) ozone anomalies associated with a descending westerly (easterly) QBO phase, which further enhances the temperature anomalies. The combination of dynamic and thermodynamic effects of the QBO in the equatorial stratosphere are associated with long-distance impacts across the stratosphere (Holton and Tan, 1980; Lu et al., 2020) and down to the surface (Garfinkel and Hartmann, 2010; Gray et al., 2018). The most well-known teleconnection of the QBO is with the polar stratosphere, since the direction of the zonal mean flow in the equatorial stratosphere modulates the propagation of extratropical waves and therefore also influences the wintertime stratospheric polar vortex (Lu et al., 2020).

However, the temperature anomaly driven by the meridional circulations impacts the height and temperature of the tropopause in the tropics (Baldwin et al., 2001; Tegtmeier et al., 2020a,b). The easterly phase of the QBO (QBOE) is associated with a higher and colder tropopause in the tropics whereas the westerly phase (QBOW) is observed with lower and warmer tropical tropopause (Tegtmeier et al., 2020a). These temperature variations near the tropopause, amongst other effects associated with the QBO, have been hypothesized to affect deep convective systems. The following section details the observational and modelling evidence that links the QBO to the tropical troposphere, as well as discusses the existing hypotheses that explain how the QBO could impact surface climate in the tropics.

2.5.2 Tropical teleconnections of the QBO

Stratospheric-tropospheric coupling refers to feedbacks and mechanistic interactions between the two bottom layers of the atmosphere. The influence of the QBO on the dynamic and thermodynamic characteristics of the tropical upper-troposphere-lower stratosphere (UTLS) region has raised interest in possible effects of the QBO over tropical deep convection and clouds, i.e., the tropical route of QBO teleconnections (Gray et al., 2018). Stratospheric-tropospheric coupling has gained attention as more evidence appears that links the QBO with tropical convective phenomena such as monsoons (Giorgetta et al., 1999; Claud and Terray, 2007), the ITCZ (Gray et al., 2018), tropical SST and cloud variability (Garfinkel and Hartmann, 2011; Davis et al., 2013), tropical cyclones (Ho et al., 2009; Jaramillo

et al., 2021) and the MJO (Son et al., 2017; Lee and Klingaman, 2018; Wang et al., 2019; Martin et al., 2021b).

Gray (1984) was amongst the first to suggest an influence of the QBO over tropical systems, in particular, that Atlantic tropical cyclone activity was enhanced during QBOW compared to QBOE. Gray et al. (1992) proposed one of the first mechanisms to link the QBO to the tropical troposphere by arguing that the anomalous vertical wind shear in the UTLS associated with the QBO affects the strength of convection in monsoonal and convergence zones to the extent that the vertical wind shear can modify ENSO and tropical cyclone frequency. Their results suggest that El Niño events are favoured during QBOE and La Niña events are more frequent during QBOW.

The evidence by Gray et al. (1992) has motivated further observational and modelling research on QBO tropical teleconnections, but no conclusive answer to cause-effect relationships has been found (e.g. Chan, 1995; Camargo and Sobel, 2010; Hansen et al., 2016). Giorgetta et al. (1999) was amongst the first to use a global climate model (ECHAM4) to investigate the effects of the QBO over tropical convection. Giorgetta et al. (1999) focused on the role that the QBO plays in modulating the strength of the East Asian and Indian monsoons. Their findings suggest that monsoon variability was partially modulated by the QBO, with strong effects over the properties of clouds at 100 hPa. Giorgetta et al. (1999) argue that these differences could be explained by the effect of the QBO on the UTLS static stability and a consequent effect over the vertical extent of deep tropical convection.

The suggestion that the QBO induces variability of the UTLS static stability is the leading hypothesis for the tropical route of QBO teleconnections (Giorgetta et al., 1999; Liess and Geller, 2012; Nie and Sobel, 2015). In short, this argument suggests the upper-level static stability, decreased under QBOE and increased under QBOW, can impact the strength of convection. The response of convection to the UTLS temperature anomalies associated with the QBO was investigated in cloud-resolving model simulations by Nie and Sobel (2015). Their experimental design varied SST boundary conditions with increments over a baseline

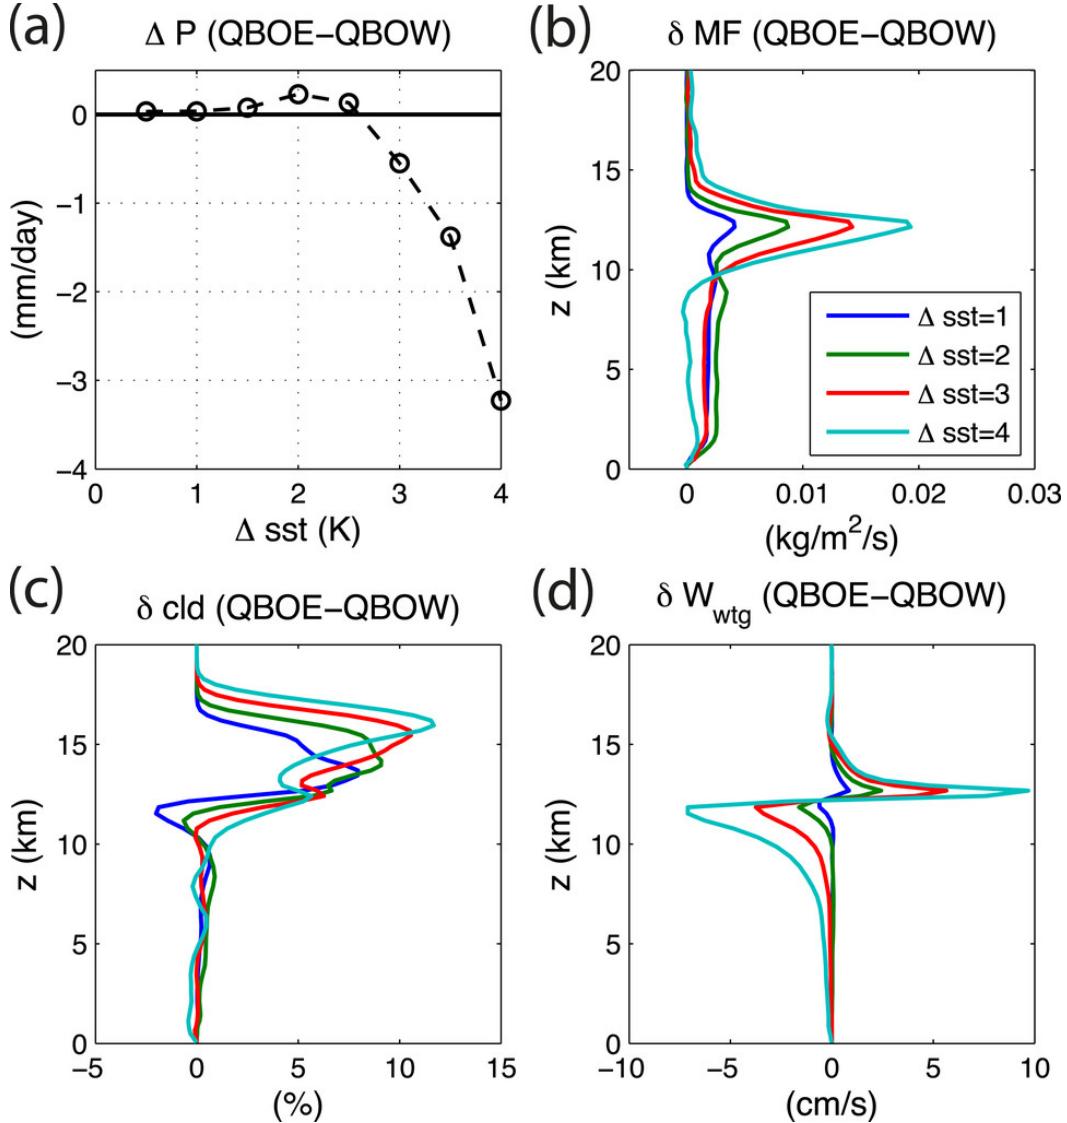

Figure 2.7: (a) QBO anomalous precipitation as a function of SST forcing. The δsst are increments over a baseline of 301 K throughout the whole model domain. (b)–(d) The differences of mass flux in cloud cores, cloud fraction, and the parametrized large-scale vertical velocity derived from the weak temperature gradient approximation, respectively, between experiments with the QBOE and QBOW temperature profiles. Figure 3 from Nie and Sobel (2015).

SST level of 301 K, using the weak-temperature gradient (WTG)¹ approximation and an idealized vertical temperature profile to simulate the effect of the QBO temperature signal.

Figure 2.7 shows that the precipitation differences between QBO phases found in their study depend on the background SSTs imposed in each simulation. The precipitation

¹The weak temperature gradient approximation makes use of the relatively small horizontal gradients of temperature and density in the tropics, which simplifies some of the primitive equations and has allowed several numerical analyses of tropical dynamics using simplified models (Sobel et al., 2001).

difference between QBO temperature anomalies is positive under relatively cool SST anomalies but in experiments with warm underlying SSTs this difference becomes negative and overall larger. The difference in mass flux and cloud fraction is also sensitive to the underlying SSTs, as increased mass flux during QBOE is increased for warmer SSTs. In other words, the QBO influence on precipitation is non monotonic and largely depends on the background SSTs.

The results of Nie and Sobel (2015) suggest that the QBO influences convection in two ways that are non-linear and that are the result of competing mechanisms. Their argument is that since the mass flux in the upper troposphere is increased during QBOE but there is also an increase in gross moist static stability (GMS) the result is an increase in the efficiency of large-scale vertical motions during QBOE for warmer SSTs, which acts to reduce precipitation. Secondly, the QBO modifies the fraction of high-level clouds resulting from deep convection which modifies the radiative heating to the column which increases precipitation during QBOE. Figure 2.7a summarises how these competing effects change for different background SSTs with the gross moist stability mechanism dominating for large SSTs. [In short, the results by Nie and Sobel \(2015\) suggest that the UTLS static stability is important in a cloud-resolving model but the impact and influence depends on the background SSTs and thus the tropospheric convective instability.](#)

One influential study by Collimore et al. (2003) analysed satellite-derived out-going long-wave radiation (OLR) in the tropics composited by QBO phase. These composites suggest that OLR is significantly different between QBO phases in most monsoon regions, such as Central America and the West Pacific, with an overall indication that convective activity is reduced during QBOW compared to QBOE. This influence, however, was not found to be zonally symmetric and in fact the longitudinal variations of the QBO-related OLR differences were suggestive enough that Collimore et al. (2003) argue for a possible role for the QBO to modulate the Walker circulation, which would explain the lack of zonal symmetry in their results.

Further modelling work has been carried out, for instance by Garfinkel and Hartmann (2010) and Garfinkel and Hartmann (2011) that investigate the effect of the QBO over tropical precipitation, the subtropical jets and the wintertime polar vortex in a GCM. Garfinkel

and Hartmann (2010) shows that the canonical ENSO teleconnections to the North Pacific are stronger during QBOW suggesting that the QBO modulates the wave propagation activity associated with ENSO events. Garfinkel and Hartmann (2011) uses perpetual winter conditions in the GCM to show that the QBO modifies the upper-tropospheric zonal wind at the equator and the strength and location of subtropical jets, as the subtropical jet is weakened during QBOE conditions.

Another relevant study by Liess and Geller (2012) found that satellite-derived cloud thickness and frequency and upper-level velocity potential had a significant and longitudinally asymmetric response to the QBO. In particular, their results show increased convective activity during QBOE in the West Pacific but the opposite for the East Pacific. For this reason, Liess and Geller (2012) also argue that the strength of the Walker circulation may be modulated by the QBO, indicating the a possible indirect of the QBO, which could explain the observed impacts of opposite signs at equatorial latitudes.

The topic of QBO tropical teleconnections has regained attention due to recent findings suggesting a link between the QBO and the MJO (Son et al., 2017) which motivated extensive research (see e.g. Lee and Klingaman, 2018; Wang et al., 2019; Martin et al., 2020) due to the worldwide impact of the MJO. The MJO in observations shows a stronger amplitude and more predictability during QBOE, but further inspection in cloud-permitting and forecast models have not provided conclusive answers to this puzzle (Martin et al., 2019, 2020).

In short, multiple lines of evidence suggest relationships between the QBO and tropical convection. The leading hypothesis for these relationships suggests that the modulation of the UTLS static stability by the QBO is strong enough to influence the strength of ascent. The effect of the QBO on vertical shear and feedbacks with the Walker circulation have also been suggested as possible explanations for the observed responses to the QBO phase.

Questions still arise as to whether this tropical link is real or due to chance, for instance Wang et al. (2019) argued that the increased predictability of the MJO under the QBOE phase is included in the initial conditions, and thus not a result of a mechanistic effect of the QBO on the MJO. More generally, there is no consensus on whether the QBO has a considerable effect on tropical deep convection. Several plausible mechanisms exist in the literature that involve a QBO modulation of wind shear, the tropopause height,

the cold-point temperature, static stability and/or feedbacks with very high cirrus and cumulonimbus clouds or the tropical circulation (see e.g Martin et al., 2021b) but more research is required to provide any definitive answers.

3

Data and methods

This thesis uses several data sources, including observational estimates of precipitation from various gridded precipitation datasets, a reanalysis dataset from the European Centre for Medium-Range Weather Forecasts (ECMWF), and CMIP6 simulations from the Met Office Hadley Centre (MOHC) models. This chapter describes these datasets, their uncertainties and addresses how these datasets will be useful to each subsequent chapter and the research questions of this thesis.

3.1 Observations and reanalysis data

Continuous and reliable observations of Earth's atmosphere and ocean have only been possible in recent decades, due to the advent of satellites. In particular, precipitation analyses have benefited greatly from satellite-derived estimates of precipitation in regions where station-data is non-existent such as over oceans. Precipitation observations are key for monsoon research and therefore for all of the chapters in this thesis. Table 3.1 summarises relevant information of the observations and reanalysis datasets used in this study and the following sections describe in detail, first, the gridded precipitation datasets and their uncertainties, and then, the reanalysis ERA5.

Table 3.1: Summary of the datasets used in this study. For each dataset, the acronym used hereafter, the period of coverage, the field used and the horizontal resolution are shown. Some datasets extend further back in time, but only the satellite-era period is used in most of the datasets. The variables used are: precipitation, surface-air temperature ($2mT$), sea-level pressure (SLP), SSTs, the x and y components of the wind (u, v), the lagrangian tendency of air pressure (ω), outgoing longwave radiation (OLR), geopotential height (GPH) and specific humidity (q).

Dataset/ Version	Acronym	Variable	Period	Data type	Resolution	Reference
Global Precipitation Climatology Project v2.3	GPCP	Precipitation	(1979-2018)	Surface and satellite	$2.5^\circ \times 2.5^\circ$	(Adler et al., 2003)
Global Precipitation Climatology Centre	GPCC	Precipitation	(1940-2013)	Surface station	$0.5^\circ \times 0.5^\circ$	(Becker et al., 2011)
Climate Prediction Center Merged Analysis of Precipitation	CMAP	Precipitation	(1979-2016)	Satellite calibrated with surface rain-gauge	$2.5 \times 2.5^\circ$	(Xie and Arkin, 1997)
Climatic Research Unit TS v4.	CRU4	Surface temperature	(1979-2017)	Surface station	$0.5^\circ \times 0.5^\circ$	(Harris et al., 2014)
Climate Hazards Infrared Precipitation with Stations	CHIRPS	Precipitation	(1981-2018)	Surface rain-gauge and satellite	$0.05^\circ \times 0.05^\circ$	(Funk et al., 2015)
Tropical Rainfall Measurement Mission 3B42 V7	TRMM	Precipitation	(1999-2018)	Satellite calibrated with surface station	$0.25^\circ \times 0.25^\circ$	(Huffman et al., 2010)
Hadley Centre SST3	HadSST	SST	(1940-2018)	Buoy and satellite	$2.5^\circ \times 2.5^\circ$	(Kennedy et al., 2011)

3.1.1 Gridded precipitation datasets

The Tropical Rainfall Measurement Mission (TRMM) dataset is a multi-satellite multi-sensor infra-red precipitation product. Several versions are available that use with different algorithms and calibrations with surface rain-gauge data (Huffman et al., 2007). This thesis uses the daily product TRMM version 7, product 3B4, provided by the Goddard Earth Sciences Data and Information Services Center (Mission, 2011) at https://disc.gsfc.nasa.gov/datasets/TRMM_3B42_7/.

A set of microwave and infra-red sensors onboard low earth orbit (LEO) satellites, such as the Microwave Imager (TMI) and the Advanced Microwave Scanning Radiometer-Earth Observing System (AMSR-E), provide the main source of information about hydrometeors for TRMM. The microwave sensor data is used to calibrate the infrared data to produce the first estimate of precipitation. However, even using the products of several satellites there is a sparse sampling of time-space precipitation in passive microwave techniques. Therefore, this data is complemented by infrared measurements onboard geosynchronous earth orbit satellites. Other sources of information include a radar onboard TRMM and rain gauge analysis. Details of the research product can be found in Huffman et al. (2007) and Huffman et al. (2010).

The Climate Prediction Center Merged Analysis of Precipitation (CMAP) dataset is a global merged product of satellite and ground-based observations but also constrained by a numerical model (Xie et al., 2007). This dataset was first produced at monthly-mean resolution (Xie and Arkin, 1997) but is now available as a collection of products at several temporal scales. The pentad-scale version of CMAP is used in this study.

The Climate Hazards Infrared Precipitation with Stations (CHIRPS) is a relatively more recent merged product of precipitation (Funk et al., 2015). This dataset uses high-resolution rain-gauge station data that is complemented by satellite cloud cold duration estimates for regions where station data is sparse. The products are calibrated with TRMM data (Funk et al., 2015), so they cannot be considered a fully independent source of information from TRMM.

All these datasets have shortcomings, advantages and uncertainties in their representation of precipitation. The algorithm of merged products, such as TRMM, that combines data from different satellite sensors as well as surface station rain-gauge data, and uses different calibration techniques for each dataset, can result in products that may have shortcomings, for example, to accurately depict extreme events (Trejo et al., 2016). In most cases, the source data of most of these datasets are shared, which means that the datasets cannot be considered to be fully independent sources of information.

The TRMM dataset has a high horizontal and temporal resolution and was used in several CMIP assessments (Geil et al., 2013; Jones and Carvalho, 2013) as a reliable source of precipitation (Carvalho et al., 2012). Therefore, this thesis used TRMM as the best estimate for the spatial and temporal characteristics of rainfall. However, the period covered by TRMM (1998-2018) is too short to analyse statistically robust teleconnections or variability, so GPCP, GPCC and CHIRPS are used to evaluate longer term variability. Although a thorough validation and comparison of these datasets across the AMS domain is missing, several studies have analysed one or more of these datasets in regions of the AMS (e.g. Franchito et al., 2009; Dinku et al., 2010; Trejo et al., 2016).

Gridded precipitation datasets will be used in all chapters throughout this thesis. In Chapter 4 these observational products are used to assess model performance, in Chapter 5 these datasets are key to illustrate the method to diagnose onset and retreat whereas in Chapters 6 and 7 they are used to evaluate observed interannual variability of precipitation.

3.1.2 ERA-5

A reanalysis is a numerical description of the state of the atmosphere on a global or regional scale with a full set of gridded diagnostics available at multiple vertical levels, in other words, "maps without gaps" (Hersbach et al., 2020). A reanalysis assimilates a physically consistent blend of observations that are used to constrain a forecasting model by relaxing the model towards these observations (e.g. Fujiwara et al., 2021). Reanalyses are key tools for climate and weather research as they provide full pictures of the atmospheric state for long periods, a feature that could not be possible with our current purely observational tools. For this reason, reanalyses are typically used to validate GCM output.

The latest reanalysis from ECMWF, the fifth generation of their reanalysis, is called ERA5. ERA5 uses the Integrated Forecasting System (IFS) model and a 4D variational data assimilation system (4D-Var), a larger number of data sources for assimilation and also provides an output on higher horizontal resolution (Hersbach et al., 2020). The driving model uses a horizontal resolution of 31 km and a vertical resolution of 137 levels from the surface to 0.01 hPa. The output is available on hourly to monthly-mean frequencies, from 1000 hPa to 1 hPa in the vertical and with horizontal resolutions as high as 0.25°. In this thesis, the horizontal resolution of all ERA5 data is 0.75° and all data was downloaded from the Climate Store at <https://climate.copernicus.eu/climate-reanalysis>.

ERA5 presents a notable improvement in the representation of the water cycle, by increasing the mean correlation to precipitation datasets such as GPCP. ERA5, as all reanalysis, resolves precipitation rates in the driving physical model using the convective scheme and parametrisation. However, this reanalysis also assimilates radiances from several satellite instruments such as Global precipitation monitoring mission Microwave Imager, the TRM Microwave Imager (TMI) and Advanced Microwave Scanning Radiometer (AMSR-2) Hersbach et al. (2020). This assimilation of satellite data has improved the representation of the water cycle in ERA5 compared to older reanalysis such as ERA-interim (e.g. Hénin et al., 2018). These improvements are also due to changes to the parametrisations of the microphysics of clouds and rain (Forbes and Ahlgrimm, 2014) and the diurnal cycle of convection (Bechtold et al., 2014).

ERA5 will be used to investigate the dynamical biases in the models in Chapter 4, the skill of the reanalysis in reproducing the mean onset and retreat dates of precipitation compared to observations in Chapter 5, the mechanisms of the MSD in Chapter 6 and of the QBO teleconnections in Chapter 7. Note that a reanalysis has large uncertainties where there is scarce data on the vertical profile of quantities such as humidity, which are crucial for most thermodynamic and dynamic processes in the tropics. However, ERA5 has sufficient vertical resolution to very reasonably represent the QBO and the associated UTLS variability (Pahlavan et al., 2021).

3.2 The Unified Model of the Met Office Hadley Centre

The UK Met Office Hadley Centre (MOHC) released the first version of the Hadley Centre Global Environmental Model (HadGEM1) in 2006 (Johns et al., 2006), and has since continuously updated the HadGEM model and submitted experiments from the model to the various phases of the Coupled Model Intercomparison Project (CMIP), which is the backbone of the Intergovernmental Panel on Climate Change (IPCC) reports. The UM is a key tool for the objectives of this thesis, and for that reason, this section first describes the model configuration used throughout this study, and subsequently describes the setup of the CMIP6 experiments.

3.2.1 The Global Coupled Configurations of HadGEM3

The MOHC Unified Model (UM) is a weather and climate global model that is based on a seamless modelling approach, which means that the UM consists of a dynamical core and parameterization schemes that can be used across a wide range of temporal and spatial scales. The UM version that was used for CMIP6 experiments and is used throughout this thesis employs the Global Coupled (GC) configuration 3.1 (GC3.1) (Williams et al., 2018; Walters et al., 2019) which in turn is composed of the components: Global Atmosphere 7.0 (GA7.0), Global Land 7.0 (GL7.0), Global Ocean 6.0 (GO6.0), and Global Sea Ice 8.0 (GSI8.0).

The GC3.1 configuration runs with 85 atmospheric levels, 4 soil levels and 75 ocean levels and can be run with atmospheric horizontal resolutions ranging from 10 - 135 km (at the midlatitudes) with varying resolutions for the ocean component as well. The model top of GC3.1 is 85 km above sea level (Walters et al., 2019). The model extends to the lower mesosphere and includes a self-generated QBO via a non-orographic gravity wave scheme that compares well with the observed QBO (Richter et al., 2020). For this reason, the MOHC UM is a particularly useful model to address the topic of the QBO teleconnections of Chapter 7.

The GA7.0 configuration, described in Walters et al. (2019), built on previous configurations principally by updating several parameterization schemes including the rain and ice-cloud treatment as well as the convection scheme. Four critical errors were pinpointed and tackled by GA7.0 which include rainfall deficits in the Indian monsoon, temperature

and humidity biases in the tropopause layer, deficiencies in numerical conservation and surface flux biases over the Southern Ocean. The GO6.0 configuration (Storkey et al., 2018) is in turn based on the NEMO ocean model code (version 3.6) and is responsible for determining the sea-ice extent, the ocean mixed-layer depth and deep water formation, amongst other key ocean processes.

In most GCMs, precipitation is a result of two simulated processes. First, precipitation due to grid-scale processes referred to as large-scale precipitation, is estimated by the microphysics, or cloud scheme, that evaluates the cloud fraction and saturation within the grid-box column where precipitation occurs by processes such as warm rain (Walters et al., 2019). The second process that simulates precipitation is associated with convection of varying depths and is considered a sub-grid process calculated by the convection scheme.

In GC3.1 the convective scheme follows three stages, according to Walters et al. (2019), first a diagnosis of the boundary layer to establish whether convection should occur at a given time-step and separately diagnoses shallow or deep convection, second, the shallow or deep convection schemes are called and third, a call for mid-level convection. In other words, the convective scheme first decides whether the thermodynamic profile at each grid-point fits certain parameters that measure the buoyancy of the parcels and vertical velocity profile, which then separates areas of deep and shallow convection. After these routines, the model implements the mid-level convection scheme to remove instabilities from above the shallow convective regions or below the deep convective regions.

The closure of the deep convective scheme follows the convective available potential energy (CAPE) closure of Fritsch and Chappell (1980) which regulates the amount, strength and duration of convection based on the availability of buoyant energy. In addition, the scheme couples the detrainment rates of plumes to the column relative humidity and buoyancy as described in Derbyshire et al. (2011). Further details of the GC3 configuration including model description and biases can be found in Williams et al. (2018) and Kuhlbrodt et al. (2018).

Table 3.2: Summary of the CMIP6 simulations in this study. The experiment, CMIP activity name, acronym model years, and number of ensemble members used in this study are presented for each simulation.

Model / Resolution	Experiment	Period	Activity	Acronym	Ens.	Reference
HadGEM3 N96	pre-industrial control	1850-2350	CMIP/DECK	GC3 N96-pi	1	(Ridley et al., 2018)

3.2.2 The CMIP6 experiments

The MOHC submitted output from several experiments to various projects part of CMIP6 using different variations of the GC3.1 configuration, i.e., varying horizontal resolution and varying representation of processes. The main model, HadGEM3 GC3.1 (hereafter GC3) is the latest version of the HadGEM model, and was run at two horizontal resolutions for CMIP6: a low-resolution configuration, labelled as N96, with an atmospheric resolution of $1.875^\circ \times 1.25^\circ$ and a 1° resolution in the ocean model and a medium resolution configuration, labelled N216¹, with atmospheric resolutions of $0.83^\circ \times 0.56^\circ$ and a 0.25° oceanic resolution (Menary et al., 2018).

The dynamical core of the GC3.1 configuration used in the submissions of HadGEM3 to CMIP6 is used in a new Earth System model that aims to better represent ocean-biogeochemical, air-soil and air-chemistry interactions, the UK Earth System Model 1 (UKESM1). The UKESM1 was recently developed aiming to improve the UM climate model

¹Note also that the vertical resolution does not change with horizontal resolution.

adding processes of the Earth System (Sellal et al., 2019). These additional components include ocean biogeochemistry with coupled chemical cycles and tropospheric-stratospheric interactive chemistry with the purpose of improving aspects of atmospheric chemistry, for example, aerosol-cloud and aerosol-radiation interactions (Mulcahy et al., 2018; Sellal et al., 2019). The physical atmosphere-land-ocean-sea-ice core of the HadGEM3 GC3.1 underpins the UKESM1, so that the UKESM1 and the HadGEM3 have the same dynamical core but the UKESM1 has the additional components mentioned above.

This study uses the output from several CMIP6 experiments, which are outlined in Table 3.2. First, the pre-industrial control (piControl) simulations, which are run with constant climate forcing that represents the best estimate for pre-industrial (1850) forcing of aerosols and greenhouse gas levels. Second, historical experiments are 164-yr integrations for 1850-2014 that include historical forcings of aerosol, greenhouse gas, volcanic and solar signals since 1850 (Eyring et al., 2016; Andrews et al., 2019a). The historical experiments of HadGEM3 and UKESM1 are composed of 4 and 9 ensemble members, respectively, but the results will be presented as the ensemble mean for the 1979-2014 period to provide a direct comparison with the observed datasets in the same period. These experiments will be referred to as GC3-hist and UKESM1-hist hereafter. For further details, Andrews et al. (2020) extensively describes the historical simulations of HadGEM3-GC3.1.

In contrast to the pre-industrial control experiments, the historical experiments use time-varying aerosol and greenhouse gas emissions and land-use change (Eyring et al., 2016). In Latin-America, land-use change for agricultural purposes has dramatically decreased tree cover in Central America and south-eastern Brazil since the 1950s (Lawrence et al., 2012), thereby affecting the surface energy balance. The regional emissions of carbonaceous aerosols, nitrogen oxides and volatile organic compound in Latin America are also considered in the historical experiments. These emissions are noteworthy, e.g., due to the impact of black carbon emissions by increased biomass burning in the Amazon and northern Central America (Chuvieco et al., 2008).

The Atmosphere Model Intercomparison Project (AMIP) is a CMIP project that uses atmosphere-only (AO) simulations of the climate to understand the role of SST biases, variability and forcing climate signals. The standard AMIP experiment covers the period

1979-2014 and uses the observed SST fields in this period to drive the models with the same forcing as the historical simulations. Other AMIP experiments may use model-driven SSTs of other experiments to disentangle other processes. This thesis uses the five ensemble members of the AMIP experiment from GC3.

3.3 The Moist Static Energy Budget

The moist static energy (MSE) measures the gravitational, sensible heat and latent heat energy within a column and is therefore conserved following air parcels under moist adiabatic processes (Neelin and Su, 2005; Back and Bretherton, 2006; Ma et al., 2019). The use of the MSE budget has proven useful to understand tropical convective phenomena such as ENSO biases (Annamalai, 2020) and teleconnections (Neelin and Su, 2005), tropical cyclones (e.g. Wing et al., 2019), the MJO (Inoue and Back, 2015), axi-symmetric monsoons (e.g. Bordoni and Schneider, 2008) and regional monsoons (e.g. Smyth et al., 2018; Ma et al., 2019), to name a few examples.

The MSE arises from the first law of thermodynamics which decomposes the internal energy of a system into two components: one associated with heat in or out of the system and the second component associated with work done by the system. The MSE, also denoted as h is given by:

$$h = Lq + C_p T + gz = Lq + s \quad (3.1)$$

where C_p is the heat capacity at constant pressure, T is the air temperature, L is the latent heat of vaporization, q is the specific humidity and s is the dry static energy. Equation 3.1 separates the total moist energy of a parcel into a dry component also referred as dry-air enthalpy or heat content (Emanuel, 2007), and the last term is the potential energy associated with the gravitational acceleration. The MSE is conserved under pseudo-adiabatic processes and thus is considered to be a key variable of a moist system, a state variable that is not created or destroyed by convection but rather re-distributed by the coupling of convection with the large-scale circulation (Chou and Neelin, 2004; Emanuel, 2007).

The MSE budget equation can be derived from adding the thermodynamic and moisture equations that arise from the primitive equation (Neelin and Su, 2005), first by writing the material derivative as:

$$\frac{Dh}{dt} = \frac{\partial h}{\partial t} + \nabla \cdot \vec{u} h_p + \frac{\partial p}{\partial t} \frac{\partial h}{\partial p} \quad (3.2)$$

where \vec{u} is the horizontal wind vector, p is the air pressure used as a vertical coordinate so that $\partial p / \partial t = \omega$. The vertically integrated budget equation arises by rearranging and integrating equation 3.2 in the pressure coordinate (Back and Bretherton, 2006; Inoue and Back, 2015; Annamalai, 2020), leading to:

$$\left\langle \frac{dh}{dt} \right\rangle = - \left\langle \vec{u} \cdot \nabla_p h \right\rangle - \left\langle \omega \frac{\partial h}{\partial p} \right\rangle + F, \quad (3.3)$$

where the angle brackets $\langle \rangle$ denote vertical integrals from the surface pressure level up to the 100 hPa level, i.e.:

$$\left\langle \right\rangle = \int_{p_0}^{100} dp, \quad (3.4)$$

and the term F denotes the net forcing of MSE which is given by the surface fluxes and the radiative heating of the column:

$$F = LH + SH + \langle LW \rangle + \langle SW \rangle \quad (3.5)$$

where SH and LH are the surface turbulent sensible and latent heat fluxes, respectively, and LW and SW are the longwave and shortwave column-integrated heating rates, respectively.

The MSE budget is particularly useful because precipitation variations can be linked to variations in individual terms of the budget in equation 3.3 due to the moisture equation (Inoue and Back, 2015; Nie and Sobel, 2015; Inoue et al., 2021). Positive increases to the right hand side of 3.3 are proportional to increased precipitation rates (Inoue and Back, 2015). For example, increased horizontal import of h , measured by $\left\langle \vec{u} \cdot \nabla_p h \right\rangle$ will lead to increased precipitation, all else being equal. Similarly, vertical transport of h , column heating and surface fluxes can all be examined individually in their contribution to precipitation

variations on multiple time-scales. For this reason, the MSE budget will be used to examine more closely the mechanisms that drive the variability of the MSD in Chapter 6.

4

The American monsoon system in UKESM1 and HadGEM3

This chapter evaluates the representation of the AMS in the CMIP6 models: UKESM1 and HadGEM3. The pre-industrial control, historical and AMIP experiments are evaluated highlighting the role of large and regional-scale biases, horizontal resolution and Earth System processes for the representation of the monsoon dynamics and teleconnections. This chapter is based on the publication: García-Franco et al. (2020) in which all the analysis was performed by the lead author.

4.1 Introduction

The response of regional monsoons to greenhouse forcing remains an open question (Zhou et al., 2016; Pascale et al., 2019) because the observational record is too short to exhibit significant trends but also because biases in GCMs increase uncertainty in future model projections. Although the thermodynamical response to greenhouse forcing in the tropics seems to be relatively well constrained, the dynamical response is less clear (Shepherd, 2014). The American Monsoon System (AMS) dynamics are shaped by regional features which means that in order to understand the precipitation response to greenhouse forcing in

a monsoon region, we need to better understand regional model biases and dynamical responses to a forcing.

The assessment of climate models in monsoon regions is key to understanding current and future changes to the water cycle in the tropics. However, and despite current recognition as a monsoon, model assessments of the AMS are scarcely done in each CMIP phase. These studies only provide a general view of the biases of each generation of models (see e.g. Geil et al., 2013; Ryu and Hayhoe, 2014). However, a deeper evaluation of individual models can be used to provide better insight into the processes associated with climatological biases in the large-scale circulation and ultimately better understand the causes for the model biases in the AMS regional features.

For example, in the South American Monsoon, CMIP5 models improved from the CMIP3 phase in their simulations of the distribution of precipitation during monsoon maturity and exhibited an improved seasonal cycle (Jones and Carvalho, 2013; Yin et al., 2013). However, some biases such as the underestimation of rainfall in the central Amazon have persisted from the first generation of GCMs up until CMIP5 (Li et al., 2006; Yin et al., 2013). The geographic distribution of rainfall during austral fall and several characteristics of the South Atlantic Convergence Zone (SACZ) and South American Low-Level Jet (SALLJ) are also poorly represented in CMIP5 in spite of their importance for the SAMS (Van Der Wiel et al., 2015; Zilli et al., 2019; Jones, 2019; Zilli and Hart, 2021). However, these studies provided little evidence as to the reasons for the improvements or the remaining biases in the models. A clear motivation to evaluate models in the South American Monsoon is that the accurate simulation of the geographic distribution and seasonality of rainfall in the Amazon rainforest is a relevant issue due to the impact of the rainforest on climate and society (e.g. Li et al., 2006; Malhi et al., 2009; Yin et al., 2013).

Climate research in recent decades has aimed to reduce uncertainty in climate projections by improving GCMs, but different approaches taken by modelling centres are seemingly disconnected (Jakob, 2014). One approach is to reduce horizontal grid spacing down to km-scale resolution to rely less on parameterizations and more on physical laws to represent clouds and convection (Palmer and Stevens, 2019). A second approach uses new explicit

representations of Earth System processes to better characterise complex land-atmosphere-ocean biogeochemical cycles that may provide a better constraint on aspects of the climate such as climate sensitivity, a parameter that depends on the carbon cycle (Marotzke et al., 2017; Sellar et al., 2019; Andrews et al., 2019a). Finally, recent modelling centres have chosen to include stochastic parametrisations of sub-grid processes since this approach has improved seasonal forecasts and may therefore improve climate projections (Palmer, 2019).

Model validation and assessment is important to analyse the effect of new parameterisations and to highlight missing processes but also evaluate which route provides the more substantial model improvement, stochastic parametrisations, increased resolution or Earth System processes. The focus of this chapter is to evaluate the CMIP6 experiments from HadGEM3 GC3.1 (GC3) and UKESM1 in the AMS. In this thesis, the AMS is considered to be composed of the North and South American monsoon systems, while also including the Midsummer drought region of southern Mexico and Central America as part of the AMS (as in e.g. Vera et al., 2006; Pascale et al., 2019).

The remainder of this chapter is organised as follows. The following section described the data and methods used in this chapter. Section 4.3 compares modelled and observed climatological temperature, sea-level pressure and low-level wind fields, whereas section 4.4 analyses the Pacific and Atlantic ITCZs. Section 4.5 analyses the spatial and temporal characteristics of rainfall and convection in the AMS while section 4.6 documents the simulated teleconnections of ENSO. A summary and discussion of the results is provided at the end of the chapter.

4.2 Methods and data

The model assessment of this chapter will use a range of experiments from the MOHC, described in section 3.2 using the HadGEM3 and the UKESM1 models. The experiments from HadGEM3 run at N96 (labelled GC3 N96) and N216 (labelled GC3 N216) resolutions are used to evaluate the role of horizontal resolution whereas Earth System Model UKESM1, which is run at N96 resolution in all the experiments, is used to evaluate the effect of representing atmospheric chemistry and other processes for the representation of the monsoon. In this

chapter, the term low resolution will refer to both UKESM1 and GC3 N96 experiments whereas medium resolution refers to GC3 N216 experiments.

The historical experiments are used to evaluate model skill in reproducing the observed period whereas the AMIP experiment from GC3 N96 is used to highlight the role of SST biases. The historical experiment data is used only in the 1979-2014 period to directly compare with the observed period. All the observational datasets used in this chapter are described in more detail in chapter 3 but in summary, the surface or near-surface air temperature data is taken from the CRU4 dataset, precipitation from TRMM, CHIRPS and GPCC and the rest of the diagnostics are from ERA5.

The climate indices of ENSO and the QBO used in this chapter were obtained by the following process. For ENSO, the deseasonalized and detrended time-series of the area-averaged SSTs (EN3.4 region [190-240°W, 5°S-5°N]) is used as an index to composite months into positive, negative and neutral phases. A month is determined to be in the positive phase (El Niño) when the index is higher than +0.65 K and a negative phase (La Niña) when the index is more negative than -0.65 K to select moderate to strong events. A neutral month is found where the magnitude of the index is smaller than 0.5 K and months with an index between 0.5 and 0.65 are discarded as they are borderline weak ENSO events or neutral cases. Other indices, including the use of a 5-month running mean (Trenberth et al., 1998), were tested without significantly changing the results. Previous studies (e.g. Menary et al., 2018; Kuhlbrodt et al., 2018) showed that the MOHC models reasonably simulate several characteristics of ENSO such as the period and SST patterns.

Principal component analysis (PCA) has shown that ENSO events may be separated into two categories: Central Pacific (CP) and East Pacific (EP) events (Cai et al., 2020), which highlight where the peak SST anomaly is found in the Pacific Ocean. PCA analysis, following Cai et al. (2020), was used on deseasonalized SST fields in the equatorial [12°S-12°N] Pacific Ocean [120°E-260°E]. The E-index is computed from $(PC1 - PC2)/\sqrt{2}$ and the C-index from $(PC1 + PC2)/\sqrt{2}$. EP (CP) events were defined where the E-index (C-index) was greater than 1.

The SACZ is evaluated in these models using the Empirical Orthogonal Function (EOF) methodology (Carvalho et al., 2004; Jorgetti et al., 2014). First, active days are constructed

by computing the first EOF of the monthly-mean deseasonalized OLR and, then, the daily OLR, previously filtered to remove periods higher than 99 days (Carvalho et al., 2004; Muza et al., 2009), is projected on the EOF pattern to produce a time series of pseudo-principal components. Active SACZ days are found when this time series of pseudo-PCs is greater than 1, and the persistence is measured as the number of continuous days where the time series is greater than 1.

Similarly, for the QBO, the deseasonalized and detrended time series of the equatorially averaged [10°S-10°N] zonal-mean zonal wind at the 70 hPa level is used as the QBO index for both reanalysis and model data. The westerly phase of the QBO (QBOw) is determined when the index is greater than 2 m s^{-1} and the easterly phase (QBOe) when the index is less than -2 m s^{-1} .

4.3 Surface temperature and low-level wind

This section evaluates how these simulations represent the near-surface air temperature and low-level wind fields in the vicinity of the AMS region (Figures 4.1 and 4.2). The biases of the historical experiments, computed as the differences between the model and observed fields, are shown in Figures 4.1c, d) for GC3 N96-hist and e, f) for UKESM1-hist. Only statistically significant differences are shown, according to a Welch t-test (Wilks, 2011). The significance for simulations with multiple ensemble members is estimated first for each ensemble member and then combined into a single probability or p-value using Fisher's method (Fisher, 1992). Pattern correlations and root-mean square error (RMSE) are shown in Figures 4.1c-f.

During DJF, the simulations show a colder-than-observed sub-tropical North America and a warm bias over the Amazon ($\approx +3.5 \text{ K}$). The west coast of South America also shows a significant warm bias ($> +4 \text{ K}$) in the historical simulations. The simulated circulation in austral summer in South America has a significant bias in the easterly flow coming from the equatorial and subtropical Atlantic. The low-level wind biases suggest a weaker easterly flow from the Atlantic into southeastern Brazil but also a strong southward flow from northern to southern South America. The South America Low-Level Jet, i.e., the low-level northwesterly flow in Bolivia, observed in Figure 1a, is stronger in the simulations. This stronger than

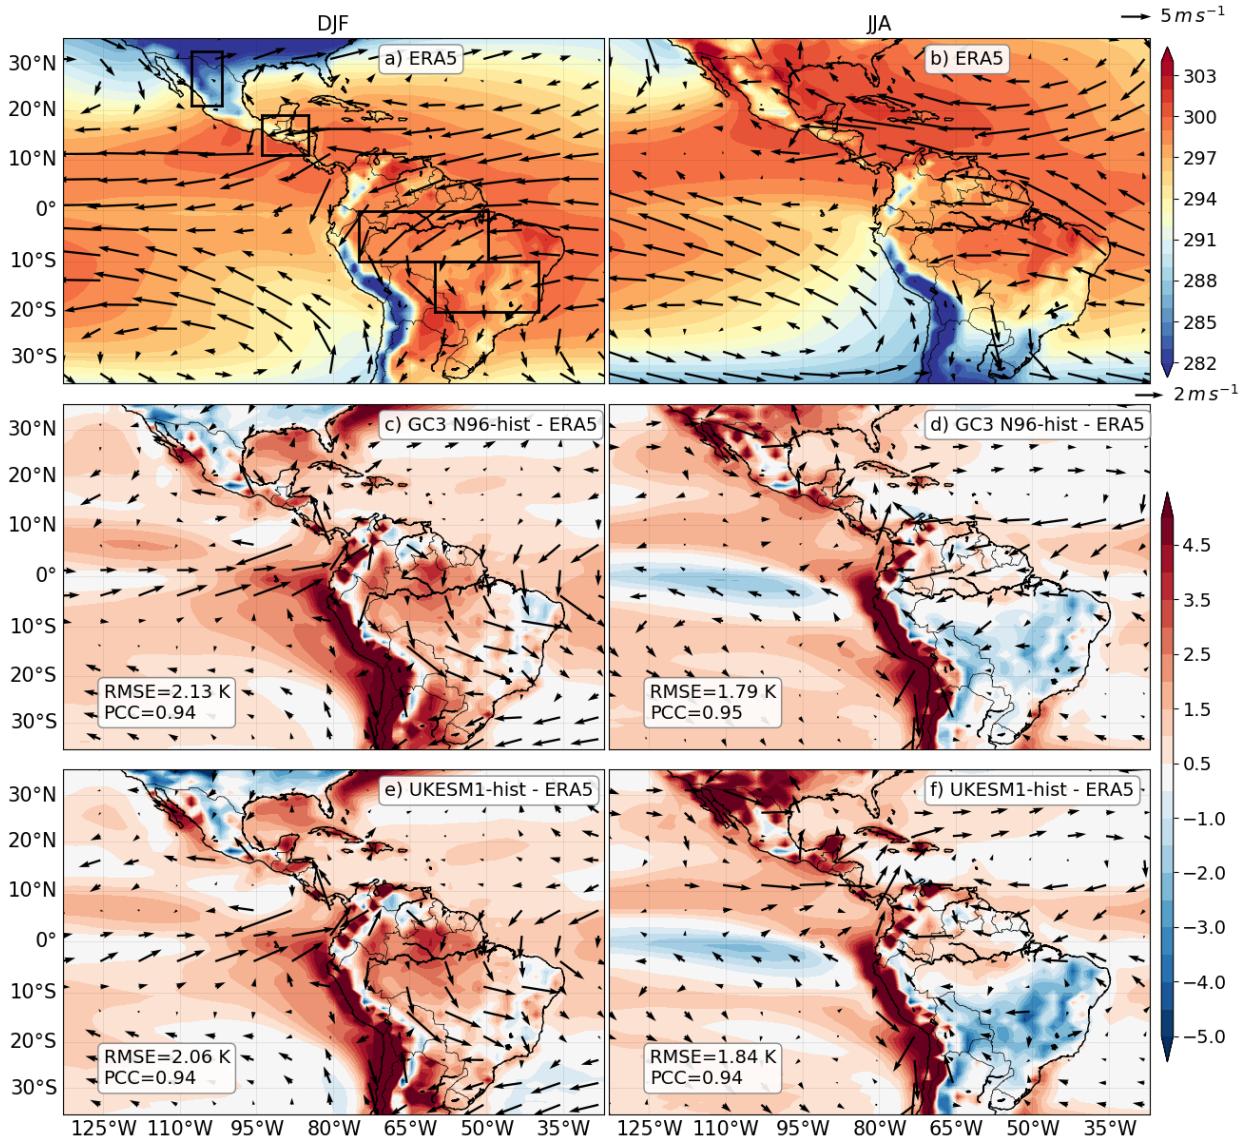

Figure 4.1: (a, b) Temperature (color-contours in K) and wind speed (vectors) at 850 hPa DJF and JJA climatologies in ERA5. The biases are shown as the differences between the ensemble mean from the historical experiment of (c, d) GC3 N96 and (e, f) UKESM1 and ERA5. The climatologies and biases are shown for (a, c, e) boreal winter (DJF) and (b, d, f) boreal summer (JJA). Only differences statistically significant to the 95% level are shown, according to a Welch t-test for each field. The key for the size of the wind vectors is shown in the top right corner of panels b) and d). The root-mean square error (RMSE) and pattern correlation coefficient (PCC) are shown on the bottom left of c-f.

observed jet is suggestive of a stronger moisture transport to the La Plata Basin, which has been associated with a drying of the Amazon and positive precipitation anomalies at the exit region of the jet (Marengo et al., 2012; Jones and Carvalho, 2018).

In turn, in boreal summer (Figures 4.1d, f), positive temperature biases are observed

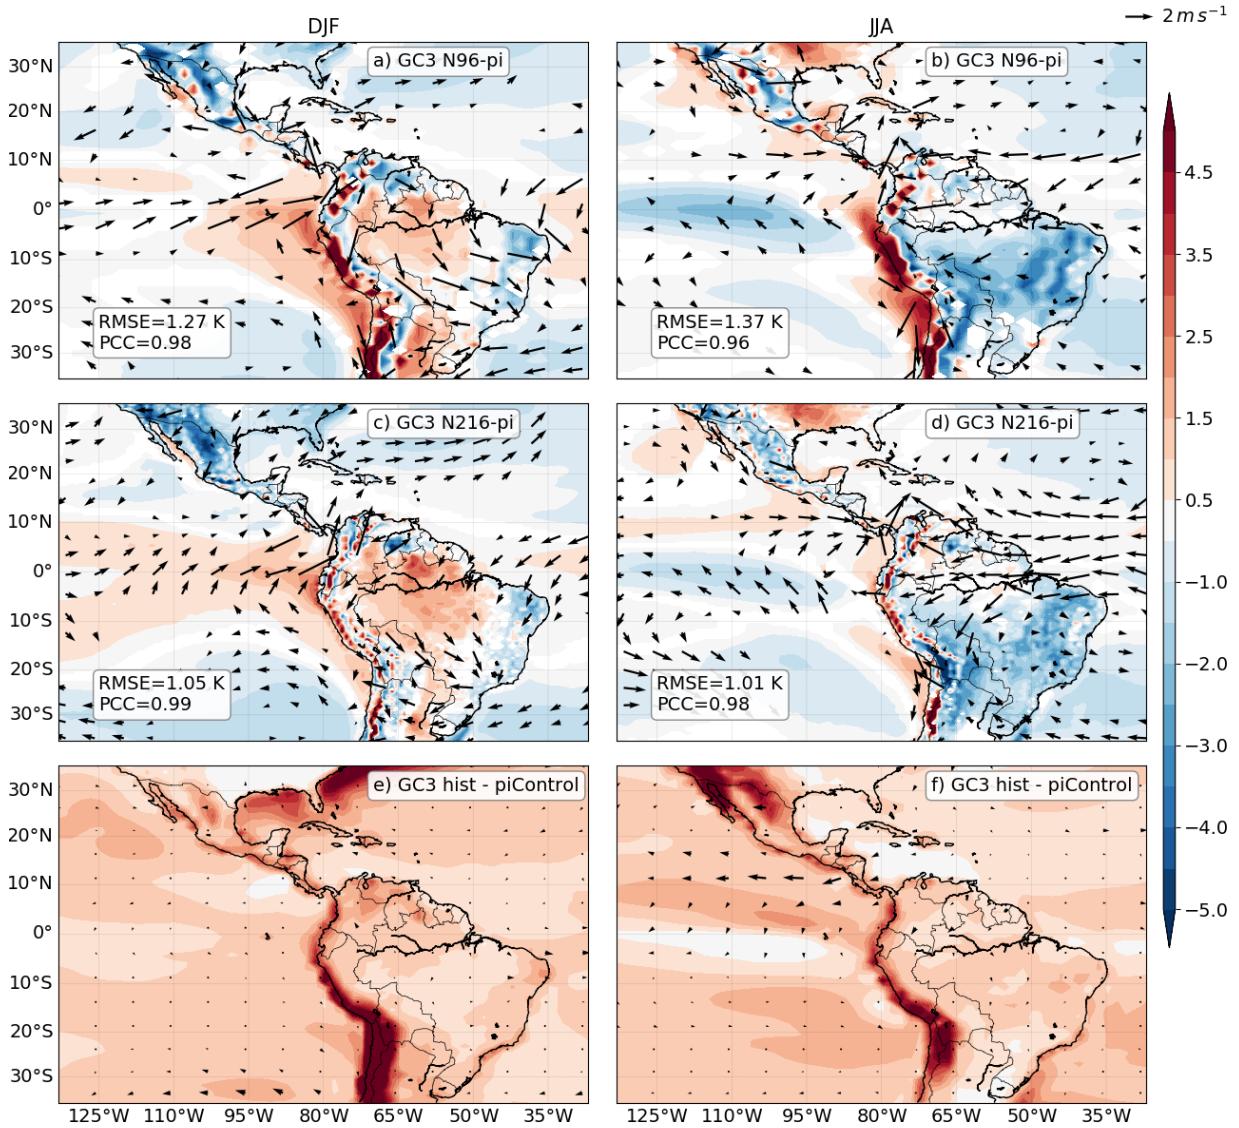

Figure 4.2: As in Figure 4.1, but showing the differences between the piControl simulations of (a, b) GC3 N96-pi and (c, d) GC3 N216-pi, and ERA5. (e, f) show the statistically significant differences between the historical (1979-2014) and piControl experiments of GC3. The RMSE and PCC are shown on the bottom left of a-d.

in southwestern North America ($> +3.5$ K), which are higher in UKESM1-hist than in GC3 N96-hist. The easterly flow west of Central America has a negative bias in UKESM1 suggesting a weaker flow that crosses from the Caribbean Sea into the East Pacific Ocean. Also in JJA, the simulated East Pacific surface temperatures are colder than observed for both historical experiments. The inclusion of Earth System processes appears to make no improvement on the low-level circulation biases.

The temperature and low-level winds in the piControl simulations (Figures 4.2a-d) are very similar to the historical simulations. In DJF, the piControl experiments simulate a warmer than observed Amazon whereas differences in the circulation in South America are essentially equal to the historical experiments. This result states the magnitude of the bias relative to the impact of forcing in these simulations. Note, instead, that these differences with observations are smallest in GC3 N216-pi, which suggests a notable impact with horizontal resolution. In JJA, the piControl simulations do not show the warmer northwestern North America observed in the historical experiments, suggesting that this feature is linked to historical forcing. However, the weaker zonal wind over the easternmost Pacific is present in both piControl and historical simulations, again suggesting that this is a notable model deficiency.

Figures 4.2e, f show the difference between the historical and piControl experiment of GC3 N96, illustrating the response to historical forcing in GC3 N96. The temperature response in austral summer in South America is observed as 1.5 K whereas in JJA in North America temperatures were 4 K higher in the historical experiment than in the piControl. The only significant difference in low-level winds, as a response to historical forcing, are the easterlies in the East Pacific Ocean during JJA, which are stronger in the historical simulation. A very similar temperature and wind flow pattern response to historical forcing was observed for UKESM1 (not shown) although of slightly different magnitude.

The seasonal cycle of temperature in key regions (depicted in Figure 4.1a) of the AMS is shown in Figure 4.3, comparing the simulations to ERA5 and the CRU4 dataset. The temperature in the North American Monsoon region ranges from the boreal winter mean temperature of 12°C to a maximum in June close to 27°C. Although the piControl simulated temperatures are colder than observed throughout the year, the models reasonably reproduce the seasonal cycle, which may be relevant for the simulated monsoon onset timing and strength (Turrent and Cavazos, 2009). The historical experiments notably show a colder than observed winter and a warmer than observed summer compared to piControl experiments.

The piControl simulations show a colder-than-observed winter in southern Mexico and northern Central America. The historical experiments show a warming signal, when compared to the piControl simulations, of about 1.5 K in winter and 2 K in the summer in

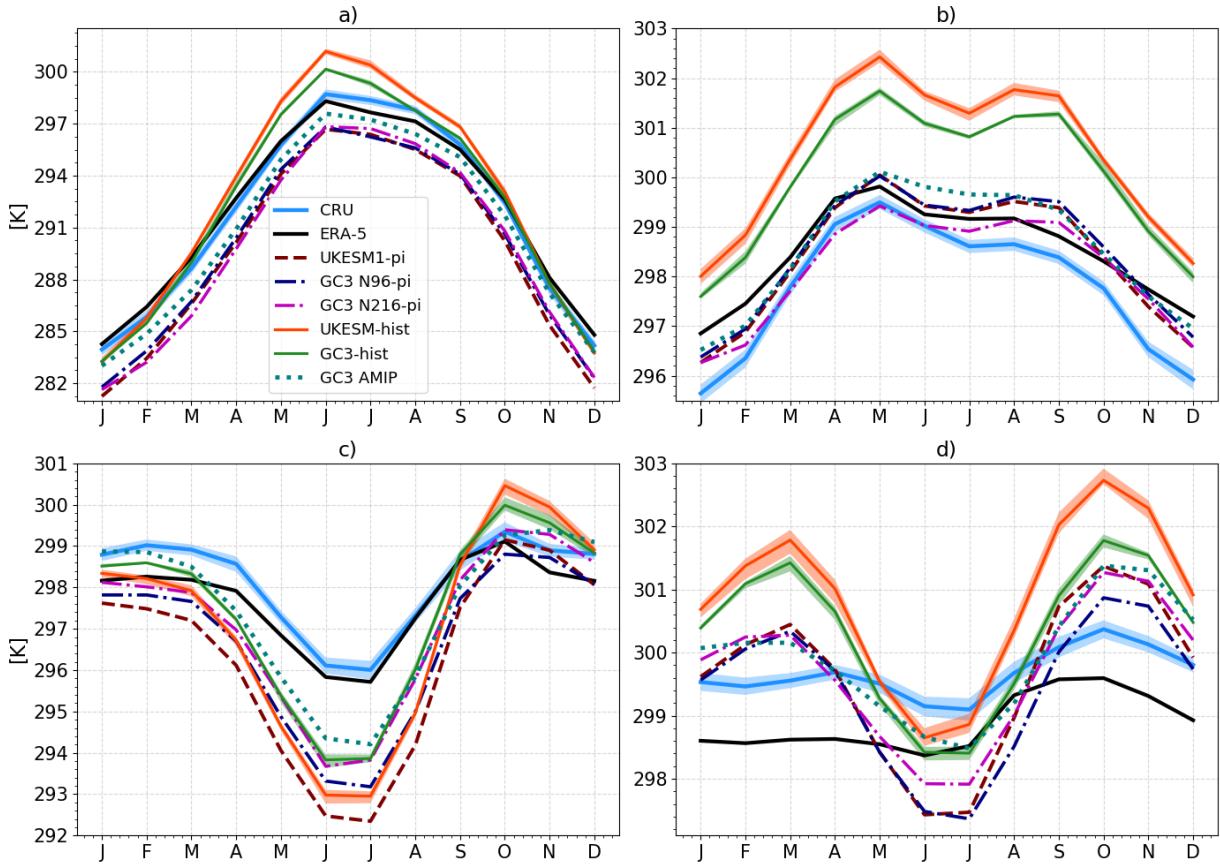

Figure 4.3: Monthly-mean temperature in the (a) North American Monsoon [$19\text{--}35^{\circ}\text{N}, 110\text{--}103^{\circ}\text{W}$], (b) the Midsummer drought [$11\text{--}19^{\circ}\text{N}, 95\text{--}85^{\circ}\text{W}$] (c) Eastern Brazil [$20\text{--}10^{\circ}\text{S}, 60\text{--}40^{\circ}\text{W}$] and (d) the Amazon basin [$-10\text{--}0^{\circ}\text{S}, 75\text{--}50^{\circ}\text{W}$] regions. The shadings for the CRU dataset represents the observational uncertainties and for the historical simulations the shading is the ensemble spread. The regions for this plot are shown in Figure 4.1a.

this region. Despite these biases, all the experiments follow closely the seasonal cycle in North and Central America.

However, the seasonal cycle in South American regions (Figures 4.3 c, d) of southeastern Brazil and the central Amazon shows notable temperature biases. The simulations show a stronger than observed seasonal cycle, especially the historical experiments. For example, the modelled temperature difference between late austral winter and spring was ≈ 4 K whereas the observed temperature varies by less than 1 K in the same period. The models show a warm bias in the Amazon region (Fig. 4.3 d) which peaks in austral spring (SON), during the development of the monsoon (Marengo et al., 2012). In southeastern Brazil, the seasonal cycle is reasonably well reproduced but with a significant cold bias throughout the

year which maximizes during austral winter (JJA), as models (e.g. UKESM1) simulate a temperature 4 K lower than observed. In all panels of Figure 4.3, the historical experiments show a significant warming signal as a response to historical forcing, which is generally stronger in UKESM1 than in GC3 N96.

The near-surface air temperature and the low-level wind structure during monsoon season are intertwined with the processes that lead to monsoon rainfall which means that the biases presented in this section will likely be related to biases in precipitation, e.g., through cloud feedbacks. For example, a biased wind structure in eastern Brazil as well as the positive warm bias in the central Amazon during DJF may indicate biases in the moisture transport and cloud cover that lead to the dry Amazon bias (Jones and Carvalho, 2013).

4.4 The Atlantic and Pacific ITCZs and the SACZ

The AMS is intertwined with the seasonal migration of the East Pacific and Atlantic ITCZ as the ITCZ largely determines regions of ascending and descending motions, moisture transport and is modulated by the hemispheric energy balance (Oueslati and Bellon, 2013; Li and Xie, 2014; Zhou et al., 2016; Cai et al., 2019). The North American monsoon and MSD regions are influenced by the East Pacific ITCZ whereas the South American monsoon is affected by the Atlantic ITCZ (Yoon and Zeng, 2010; Marengo et al., 2012). Three simulations are evaluated in this section: two low-resolution (N96) runs, the ensemble-mean UKESM1-historical, the ensemble mean GC3 AMIP and a medium-resolution run, GC3 N216-pi. Other simulations are not shown as all the coupled low resolution (N96) simulations from UKESM1 and GC3 N96 showed very similar precipitation and ITCZ characteristics whereas the AMIP and medium-resolution experiments showed notable differences to the rest.

The climatological ITCZ in TRMM (Figure 4.4a) is found, on average, at 8°N in the East Pacific and at 6°N in the Atlantic. All the simulations reasonably represent the climatological position of the East Pacific (EP) ITCZ; however, the modelled Atlantic ITCZ near the coast of Brazil is found south of the equator at 3°S in the coupled model simulations. The location of the ITCZ in GC3 N216-pi and the spatial distribution of rainfall is more consistent with TRMM dataset than the rest of experiments. Rainfall near

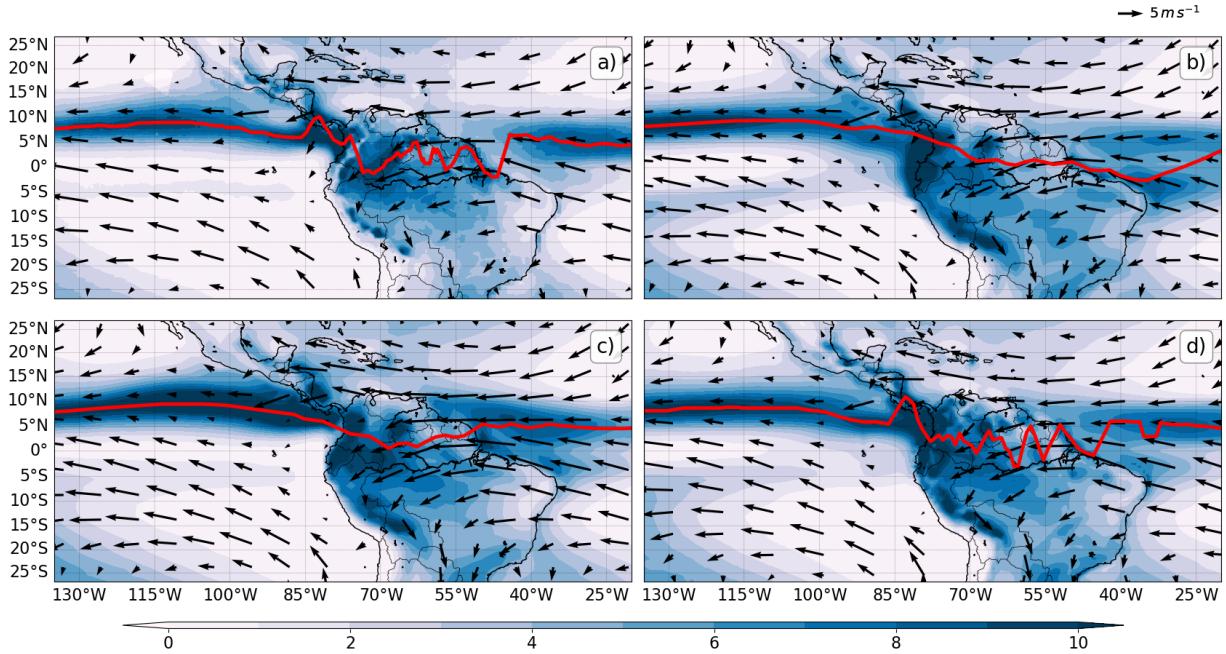

Figure 4.4: Climatological precipitation [mm day⁻¹] and low-level wind speed (850-hPa) in (a) TRMM and ERA-5, (b) the ensemble-mean UKESM-historical, (c) GC3-amip and (d) GC3 N216-pi. The red line highlights the maximum rainfall for each longitude as a proxy for the position of the ITCZ.

the Amazon river mouth is significantly larger in the low-resolution simulations than in the TRMM dataset. However, the GC3 AMIP shows the best agreement with TRMM in ITCZ position and rainfall distribution.

The seasonal cycle of the ITCZ location, precipitation rates and low-level winds in both basins are shown in Figure 4.5, for TRMM, UKESM1-hist, GC3 AMIP, GC3 N96-pi and GC3 N216-pi. The seasonal march of the ITCZ closely follows meridional migration of the solar insolation and the regional SSTs (Doi et al., 2012; Donohoe et al., 2013). An accurate representation of this migration requires a reasonable simulation of the coupling of the low-level circulation and local cross-equatorial SST gradients (Chiang et al., 2002; Hastenrath, 2006; Richter et al., 2014).

The EP ITCZ in observations (Fig. 4.5a) migrates southwards during the first days of the year and is weakest and at its southernmost position at 5°N around day 100 (mid-April). During boreal spring, the EP ITCZ migrates northward reaching a peak latitude and maximum rainfall at 10°N by day 250, or early September. The EP ITCZ during boreal winter is weaker than during the rest of the seasons. The low-level winds are predominantly

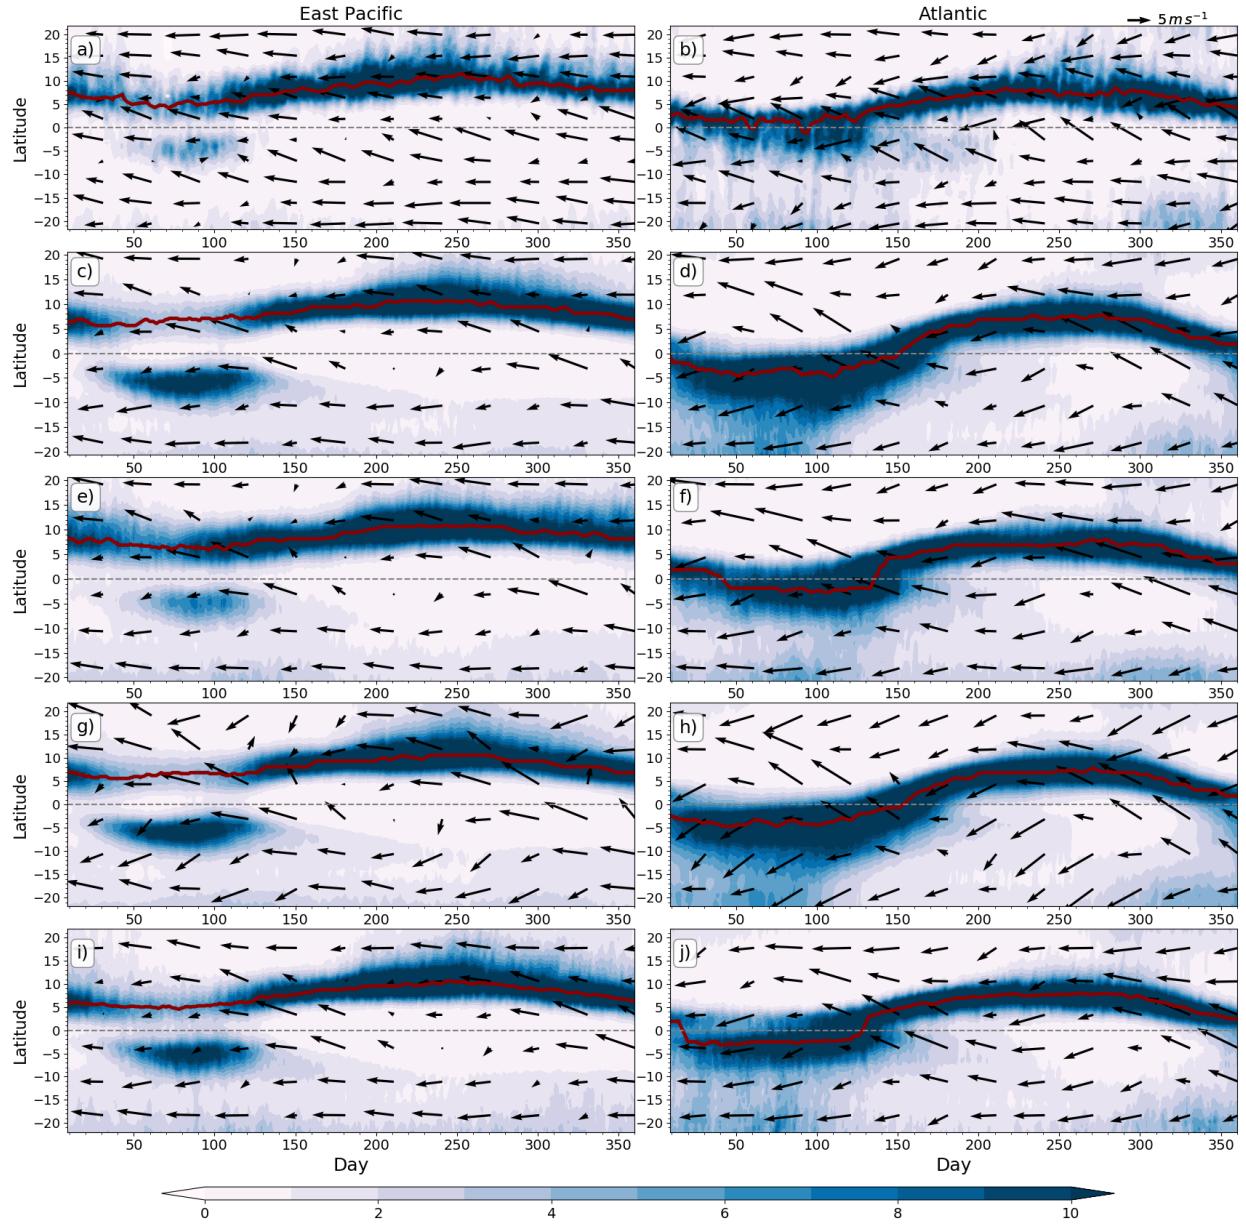

Figure 4.5: Time-Latitude plot of daily mean rainfall (colour contours) and low-level wind speed (850 hPa) longitudinally averaged over the (a, c, e, g) East Pacific [150°W - 100°W] and (b, d, f, h) Atlantic [40°W - 20°W] Oceans. (a, b) show rainfall from TRMM and winds from ERA-5, (c, d) the ensemble-mean UKESM-historical, (e, f) GC3 AMIP, (g, h) GC3 N96-pi and (i, j) GC3 N216-pi. The red solid line shows the ITCZ as the latitude of maximum precipitation.

easterly, which are stronger away from the ITCZ and weaker and convergent near the ITCZ position. The position and seasonal migration of the EP ITCZ is reasonably well represented in the four simulations (Fig. 4.5), but a noticeable bias in precipitation is observed in boreal winter south of the equator in the coupled simulations. The modelled low-level wind biases

are characterized as stronger winds converging toward the ITCZ during boreal summer and spring and diverging away from the equator during boreal winter.

The Atlantic ITCZ (Figure 4.5b) has a similar seasonal cycle to the EP ITCZ, located at 4°N at day 1 and migrates southwards at the start of the year reaching its southernmost position at 0° at the end of March. During boreal spring, the Atlantic ITCZ migrates north, reaching 8°N at the start of boreal summer. In contrast to the EP ITCZ, the maximum rainfall in the Atlantic ITCZ does not weaken during any season. The position of the modelled ITCZ is generally biased south with respect to the observations.

The simulated ITCZ crosses south of the equator during boreal winter, with maximum precipitation rates of 12 mm day⁻¹ found in the 0-10°S region. After boreal spring, the modelled ITCZ crosses back north of the equator and matches the observed ITCZ reasonably well for boreal summer and fall. Low-level wind vectors near the Atlantic ITCZ (Figures 4.5f and h) suggest a southerly bias north of the equator and a northerly bias south of 10°S. Note that although there is a clear southward bias of the boreal winter ITCZ in this model, the GC3 N216-pi is top ranked amongst the CMIP6 cohort in the representation of the low-level

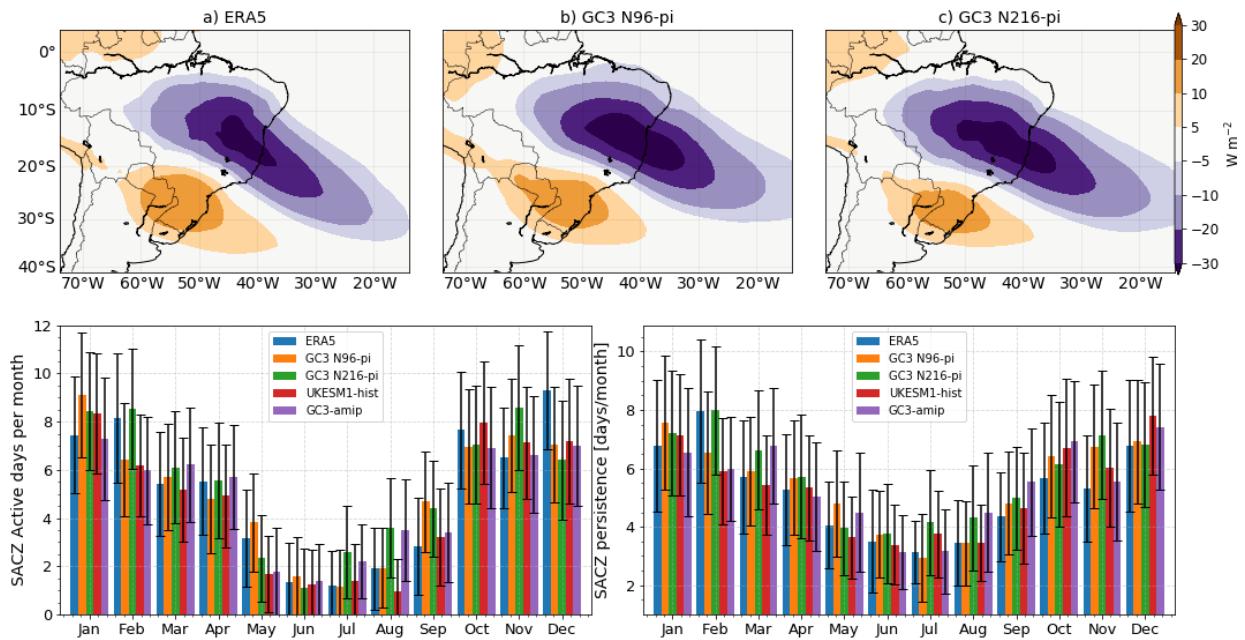

Figure 4.6: (a, b, c) OLR anomalies during active South Atlantic Convergence Zone (SACZ) events. (d, e) Frequency of active SACZ days and length of active SACZ events in reanalysis and model data, the standard deviation is shown as the error bar.

trade winds and the SST gradients throughout the Atlantic (Richter and Tokinaga, 2020).

The SACZ is a key element of the climate of the SAMS (Carvalho et al., 2004; Jorgetti et al., 2014; Van Der Wiel et al., 2015; Zilli et al., 2019) that is not frequently assessed in climate models. The mean representation of the SACZ features in these simulations, defined by the OLR empirical orthogonal function analysis (see section 4.2), closely resembles the pattern found in ERA5 (Figure 4.6). The SACZ active days and the persistence of the SACZ are also compared and found to be in relatively good agreement between reanalysis and model datasets.

The simulations from UKESM1, and GC3 N96 and N216 appear to reasonably simulate the spatial pattern of active SACZ days characterized by the low OLR in southeastern Brazil and higher OLR in the La Plata Basin. Similarly, the seasonal cycle of the frequency and persistence of SACZ active days is very well represented by the models with peak activity found from November through January and very little activity during austral winter. The impact that an accurate representation of the SACZ activity in GCMs has for representing short-scale variability of the South American Monsoon System is an open question, as the SACZ is rarely assessed in CMIP analyses.

GCMs have showed little improvement in their representation of ITCZs in CMIP phases(Oueslati and Bellon, 2015) and this section shows that these biases are also found in these CMIP6 experiments. These biases are hard to improve because the position, strength and seasonal migration of the ITCZ are controlled by ocean-atmosphere feedbacks that intertwine the local and regional circulation with cloud-radiative feedbacks and the atmospheric and oceanic transport of energy (Schneider et al., 2014; Oueslati and Bellon, 2015; Byrne and Schneider, 2016; Byrne and Zanna, 2020). Nevertheless, recent assessments of all CMIP6 models indicate that these MOHC simulations are top ranked in the representation of both the Atlantic and East Pacific SST and ITCZs (Tian and Dong, 2020; Richter and Tokinaga, 2020). Therefore, the model is a suitable tool to explore the simulation of monsoon precipitation, which is the following section, whilst keeping in mind the possible impacts that these biases may have on other aspects of the tropical climate.

4.5 Precipitation and convection in the AMS

4.5.1 Mean seasonal precipitation

The austral summer (DJF) rainfall distribution in South America (Figure 4.7) shows several noteworthy biases in the coupled simulations compared to TRMM. The maximum austral summer rainfall in TRMM (Fig. 4.7a) is found in a northwest-southeast oriented band from the core Amazon region into southeastern Brazil, the SACZ. One main bias (Figs. 4.7e-h) is the southward displacement of the Atlantic ITCZ, observed as positive ($+5 \text{ mm day}^{-1}$) biases south of the equator and negative biases (-5 mm day^{-1}) north of the equator in the Atlantic. The models underestimate rainfall in the core Amazon basin by -3 mm day^{-1} on average, and rainfall in southeastern Brazil is overestimated by more than $+5 \text{ mm day}^{-1}$, approximately +100% of the observed rainfall in this region.

The precipitation biases are associated with a stronger northerly flow in South America, transporting moisture from the Amazon into southeastern Brazil and the La Plata Basin. The magnitude of these biases is smaller in GC3 N216 (Fig. 4.7f) than in the low resolution simulations, such as UKESM1-hist. The ensemble mean GC3 AMIP (Fig. 4.7d) shows a better representation of the austral summer rainfall and circulation patterns, removing the main circulation biases (Fig. 4.7g) of the coupled simulations. The response to historical forcing, illustrated by the difference between UKESM1-hist and UKESM1-pi (Fig. 4.7h), is much weaker than the magnitude of the biases and is characterized by a weak drying of the Amazon and southeastern Brazil. Therefore, the magnitude of these biases are too large to have confidence in these drying responses to historical forcing.

The modelled and observed JJA mean rainfall and biases for Mexico and Central America are shown in Figure 4.8. The main feature is the East Pacific (EP) ITCZ which extends north to 15°N near the western coast of Mexico as a broad band of rainfall ($>11 \text{ mm day}^{-1}$). The modelled EP ITCZ (Figures 4.8e, f, g) rainfall is overestimated by more than 5 mm day^{-1} , especially in GC3-amip. This wet bias is associated with a westerly bias in the low-level circulation, suggesting a weaker flow from the Caribbean into the East Pacific.

The North American Monsoon can be observed as a band of precipitation across western Mexico. In the core monsoon region, near the Sierra Madre Occidental (Adams and

Comrie, 1997; Zhou et al., 2016), the JJA-mean rainfall is higher than 8 mm day^{-1} . The distribution of rainfall in the North American Monsoon region is relatively well represented

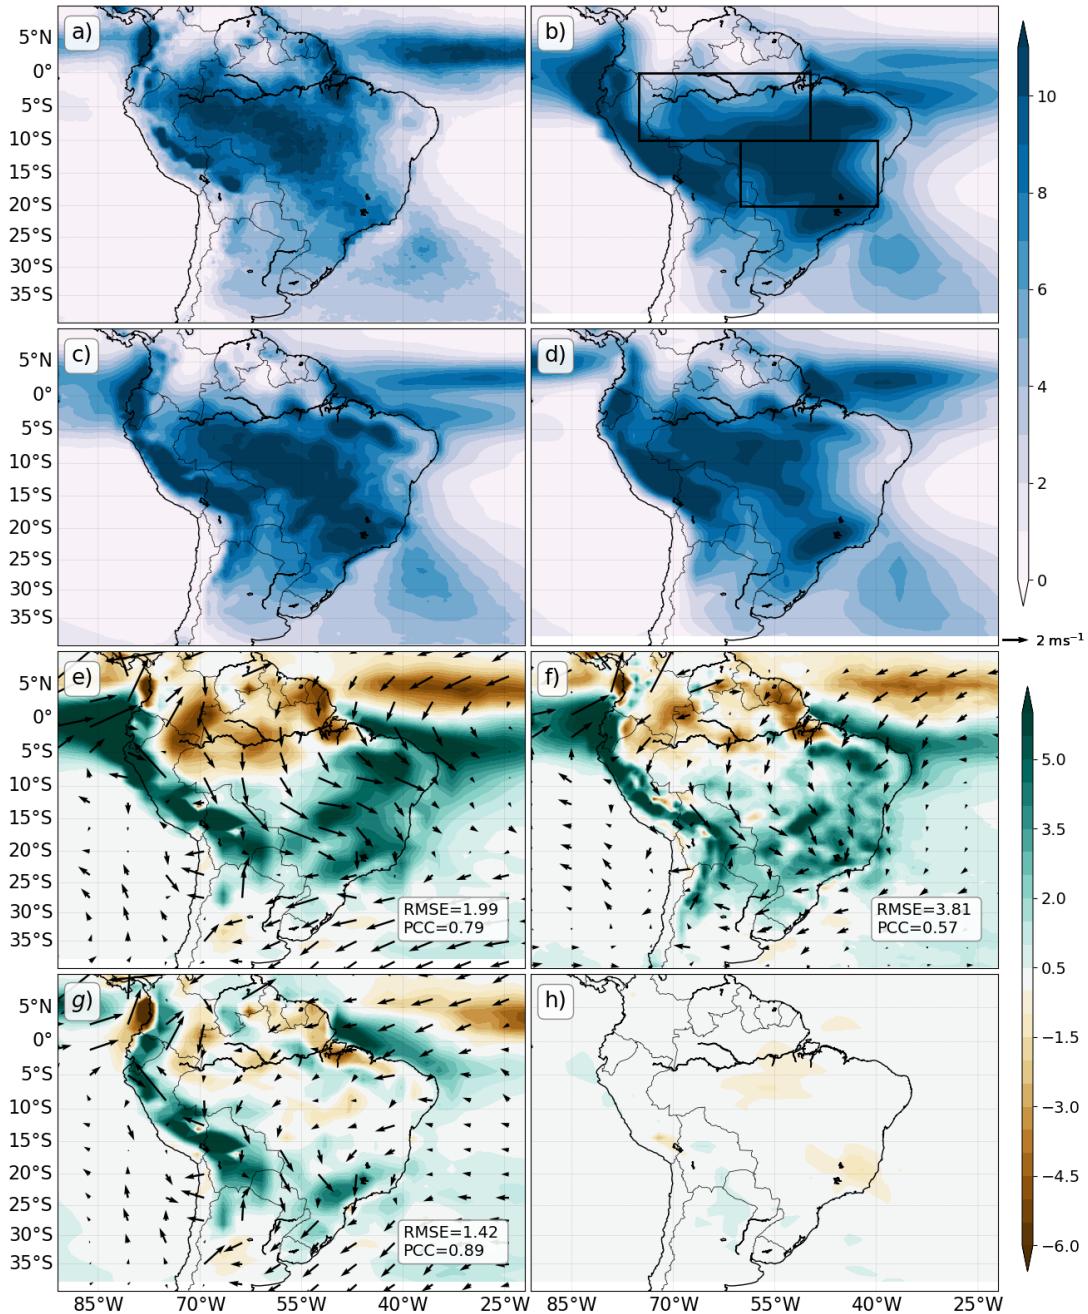

Figure 4.7: DJF mean rainfall [mm day^{-1}] from (a) TRMM, (b) UKESM1-historical, (c) GC3 N216-pi and (d) GC3-ampi. (e, f, g) show the statistically significant biases, i.e., differences between panels (b, c ,d) and (a) TRMM. (h) Precipitation difference between UKESM1-historical and UKESM1-pi, only statistically significant differences (95% confidence level) are shown. In (e-g) in the 850-hPa wind biases are shown as vectors.

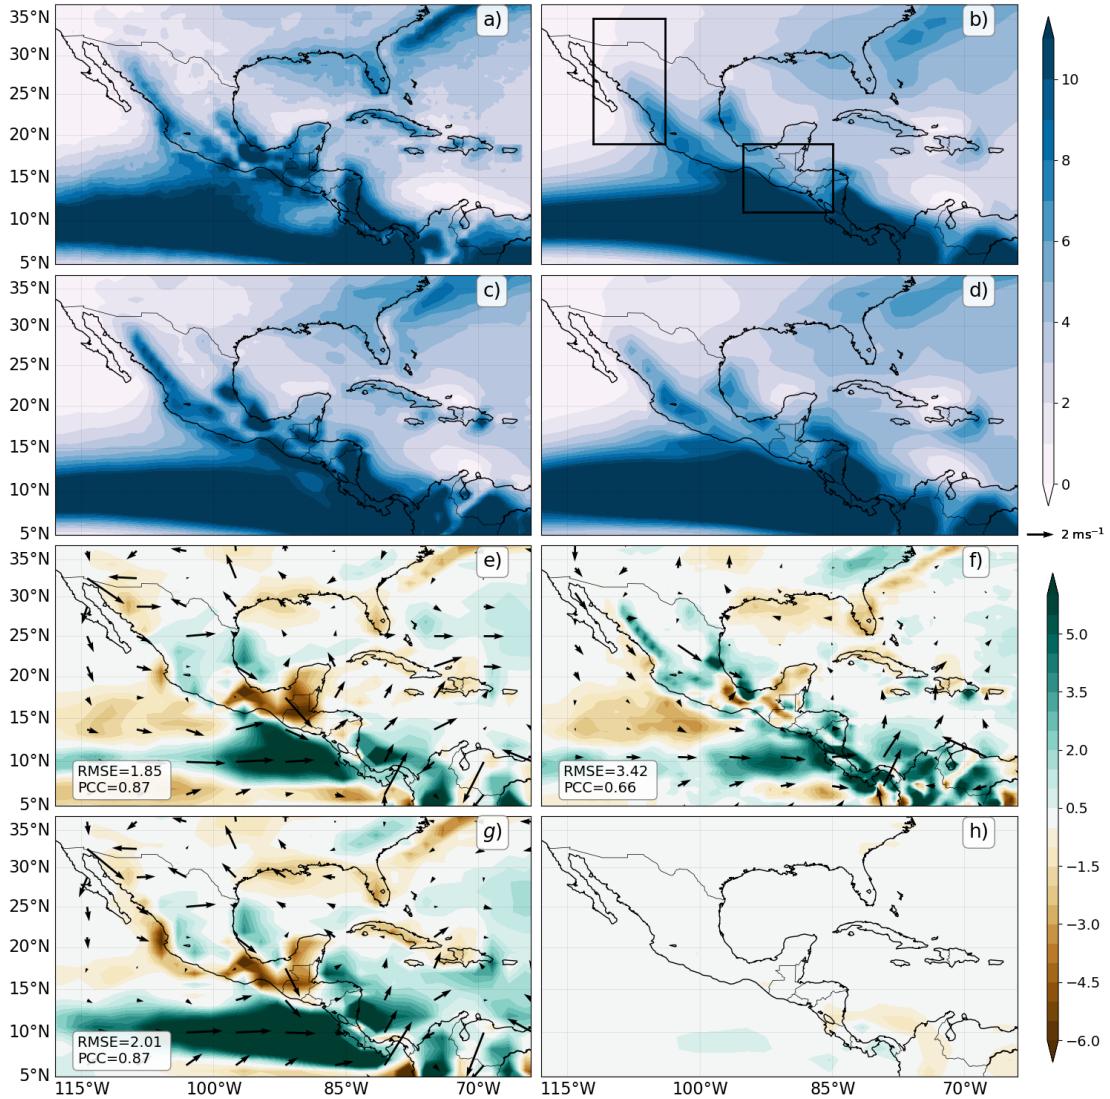

Figure 4.8: As in Figure 4.7 but for JJA in the northern part of subtropical America.

in all the simulations, as only a moderate wet bias ($+2 \text{ mm day}^{-1}$) in western Mexico is observed. The northernmost part of the North American Monsoon (southwestern US) is best simulated by GC3 N216-pi, as the other simulations show a dry bias in this region. The low-resolution simulations (Figure 4.8e) underestimate rainfall (-5 mm day^{-1}) over land in southern Mexico, Guatemala and Belize. Rainfall in the Caribbean islands and Florida is underestimated (-1 mm day^{-1}) in all simulations.

In most cases for JJA in this region, the precipitation and wind biases were reduced in the medium-resolution simulation (Figure 4.8f) and little-to-no difference was observed between UKESM1-hist and GC3 N96-hist (not shown). The precipitation response to

historical forcing is much lower than the biases (Figure 4.8h) with no significant precipitation differences over land due to the historical forcing.

4.5.2 The annual cycle of rainfall

Figure 4.9 shows the seasonal cycle of rainfall at the pentad (5-day) scale over the North American Monsoon, the Midsummer drought (MSD), the Amazon and eastern Brazil regions. The correlation between TRMM and the model and reanalysis data (ERA5) is also shown in each panel.

The seasonal cycle of precipitation in the MSD region in the simulations is well represented as all the simulations show the characteristic bimodal distribution, a feature that is difficult to simulate for a climate model (Ryu and Hayhoe, 2014). However, the magnitude of the first peak and second peaks of precipitation in the simulations are different. Most of the simulations show a wetter first peak than TRMM by 4 mm day^{-1} , and the AMIP simulation

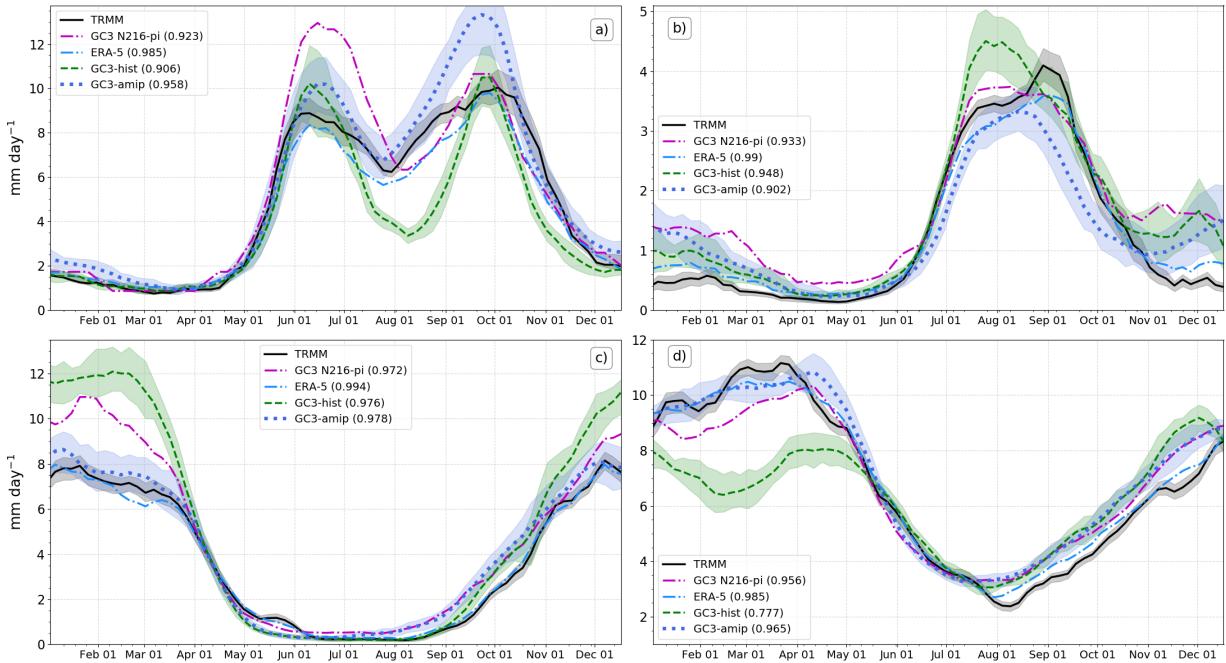

Figure 4.9: Annual cycle of pentad-mean rainfall in the regions (a) the Midsummer drought, (b) the North American Monsoon, (c) Eastern Brazil and (d) the Amazon Basin. The regions are defined as in Figure 4.3 and are illustrated in Figure 4.8b and Figure 4.9b. The shaded regions represent observational uncertainty for TRMM and ensemble spread for the historical experiments. The correlation coefficient for each of the simulated seasonal cycles with TRMM is given in brackets in each panel.

overestimates the second maximum of rainfall by 2-3 mm day⁻¹. Similarly, the differences between the first peak and the MSD and between the MSD and the second peak are more pronounced in the simulations. The timing of the MSD period is different in the models, as the simulations show the driest period taking place 10 days after TRMM and ERA5.

In the North American Monsoon (Figure 4.9b), the observed seasonal cycle is characterized by a very long dry period from the November to June, which is followed by a sharp increase of rainfall around mid-June. The timing and strength of the onset of rainfall is well represented by all these simulations. Moreover, the modelled and observed mean precipitation rates during monsoon maturity are 4 mm day⁻¹, from mid-July until early September, which suggests the models can also reproduce the observed peak monsoon rainfall. The historical simulations show a shorter wet season characterised by an earlier retreat of the monsoon rainfall and a positive bias (+1 mm day⁻¹) is found during late local fall and early winter, a feature present in most CMIP5 models (Geil et al., 2013).

The seasonal cycle of precipitation in eastern Brazil is characterised by a very wet summer (~8 mm day⁻¹) compared to a very dry (~0.2 mm day⁻¹) winter (Figure 4.9c). The models (Figure 4.9c) show a positive bias during monsoon maturity. This bias was found to be of +4 mm day⁻¹ and +2.5 mm day⁻¹ for the low and medium resolution simulations, respectively. This positive bias in the maximum rainfall is consistent with the biases shown in Figure 4.7, which showed that rainfall in southeastern Brazil is overestimated, especially in the low resolution coupled simulations. In contrast to the coupled simulations, GC3-amip shows a very good agreement with the observed maximum summer rainfall and the seasonal cycle ($r=0.978$) throughout the year.

Finally, the seasonal cycle in the Amazon (Figure 4.9d) has a weaker seasonal contrast as relatively large precipitation rates (>2 mm day⁻¹) are found year-round. The coupled simulations show a dry bias during austral summer and a good agreement with the observations during austral winter. Rainfall rates in the Amazon from January to March, in both TRMM and ERA-5, are close to 10 mm day⁻¹, yet the low resolution simulations show rainfall rates of 8 mm day⁻¹ in mid-February. [GC3 N216-pi shows a better agreement with observations than the low resolution coupled simulations, which points to the role of horizontal resolution](#), but still underestimates austral summer rainfall by 1 mm day⁻¹. The

models, however, represent with reasonable skill the timing of the transition from early austral spring (4 mm day^{-1} in September) to summertime rainfall (6 mm day^{-1} in November).

The dry Amazon bias has been a known feature of GCMs, including the MOHC models, since CMIP3 (Li et al., 2006; Yin et al., 2013). In these simulations the dry Amazon bias is only alleviated in GC3-amip whose seasonal cycle and maximum summer rainfall agree well with observations suggesting that the Atlantic SST biases, which couple to the moisture transport between ocean and land, are the key factor for the biases in the Amazon in coupled model simulations.

4.5.3 Characteristics of convective activity

The seasonal cycles of outgoing long-wave radiation (OLR), vertical velocity (ω) and specific humidity (q) characterise how the strength and height of deep convection, as well as the moisture within the column vary with the wet season in a monsoon region. The pentad-mean annual cycle of OLR, q and ω at the 500-hPa level in four regions of the AMS (Figure 4.10) are used as process oriented diagnostics to further evaluate the biases in the seasonal cycle of rainfall.

For the North American Monsoon the seasonal cycles of OLR, q and ω are relatively well represented in the simulations. During late boreal winter and early spring, OLR increases steadily as a result of surface warming. However, in early June, near the onset date (Douglas et al., 1993; Geil et al., 2013), OLR sharply decreases reaching a minimum value of 246 W m^{-2} by mid-July. The vertical velocity decreases steadily from January to a minimum in August, indicating ascent from May 1st until September 15th. The models show similar seasonal cycles but overestimate the summertime OLR by $\approx 6 \text{ W m}^{-2}$ and underestimate mid-level moisture by 0.3 g/kg and ω by 0.01 Pa s^{-1} which is about 5-10% overall. The simulated shallower convection and drier mid-troposphere is seemingly compensated by stronger mid-level ascent leading to reasonable precipitation rates.

In the MSD region, OLR and q show signs of convective activity from mid-April, as OLR sharply decreases and moisture increases. The characteristic MSD bimodal distribution of precipitation can also be observed as two troughs of OLR, and ω and two peaks in q separated by a period of relatively higher OLR, lower q and weaker ascent from June 15

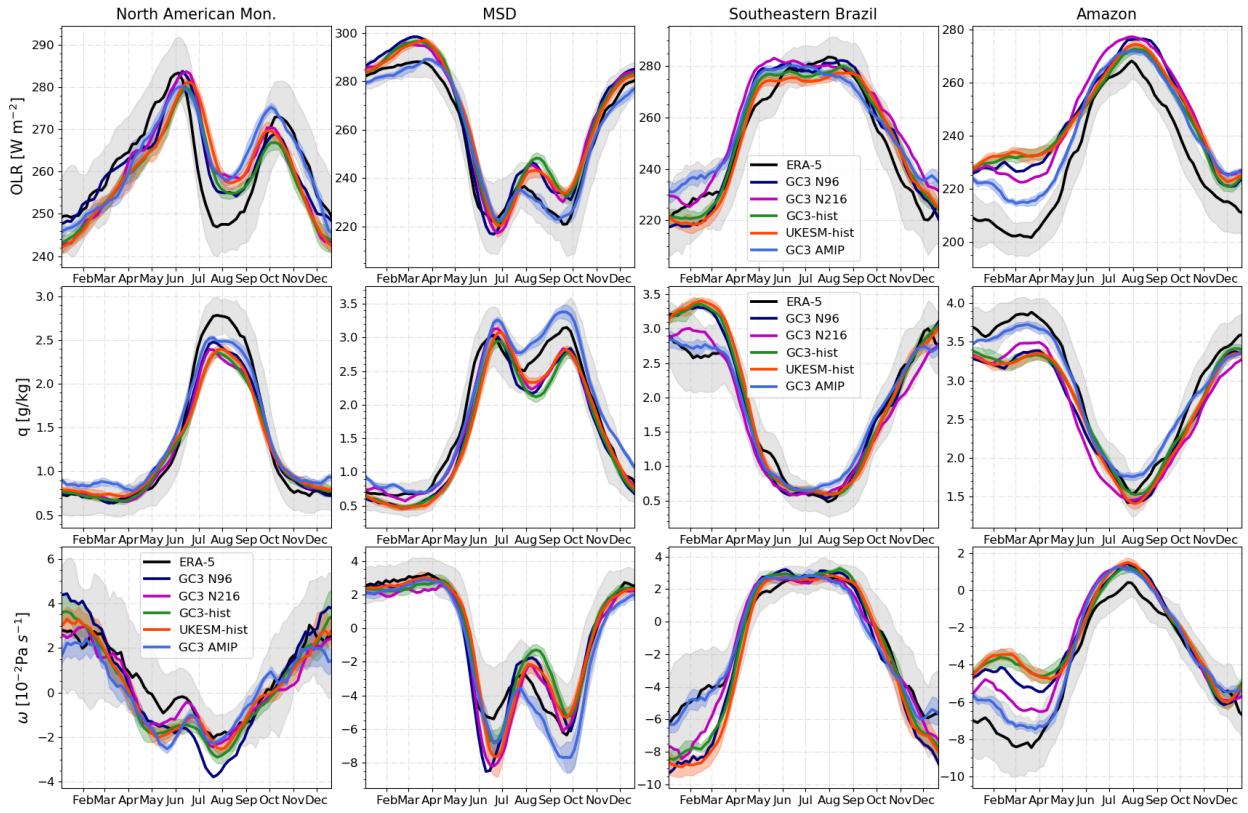

Figure 4.10: Pentad-mean (upper) outgoing long-wave radiation (OLR), (middle) specific humidity at 500-hPa and (lower) ω 500-hPa. These are shown from left to right for the North American Monsoon, the Midsummer drought, southeastern Brazil and the core Amazon. The uncertainty in ERA-5 data, shown as faint gray shading was estimating by bootstrapping with replacement the ERA-5 record 10,000 times.

until late August. Although arguably with a small dry bias with shallower convection after mid-July, the simulations follow closely the observed seasonal cycle.

The simulated conditions during the first peak period show similar OLR and mid-level moisture but stronger ascending motions, which may explain the positive rainfall bias in this period (Fig. 4.9a). In the period between the first peak and the MSD, the simulated OLR increases more sharply than observations from 220 W m^{-2} (June 15) to 250 W m^{-2} (early August), with similar behaviour in q and ω , which may also be related to the strong variations of precipitation within the rainy season in the simulations. The period during the second peak of rainfall in September shows signs of shallower convection and a drier mid-level when compared to ERA5.

In southeastern Brazil, the simulations reasonably follow the timings of the annual cycle

of OLR, q and ω of the reanalysis, particularly during austral winter. The moisture q in ERA5 during the dry seasons of austral fall, winter and spring is reasonably simulated by all the experiments. However, during austral summer, the coupled model simulations show significant biases characterised by stronger ascent and increased specific humidity in the mid-levels, although the height of convection (OLR 225 W m^{-2}) is only modestly higher in the simulations.

The simulated OLR, q and ω exhibit the highest biases in the Amazon. During austral summer, particularly January and February, the simulated convective activity is shallower (OLR bias of $+25 \text{ W m}^{-2}$) and weaker (positive ω bias $+0.02 \text{ Pa s}^{-1}$) and the mid-level troposphere is drier (-0.5 g/kg) than in ERA5. All these biases are in agreement with the dry Amazon bias described in the previous section. Despite biases in the magnitude of OLR, q and ω during peak convective activity, the seasonal variation is very well simulated so that convective activity, as evidenced by these metrics, starts and ends in the simulations within one or two pentads of the reanalysis.

The smallest biases in the coupled simulations are those of GC3 N216-pi, for all the regions. The simulated OLR, q and ω in GC3-amip in southeastern Brazil and the Amazon show a much better agreement with the reanalysis during austral summer than the rest of the simulations. This section shows that while precipitation may be well represented in a region, e.g., the North American monsoon, competing model biases in the strength of convection and moisture may lead to a right representation of precipitation.

4.6 ENSO Impacts

El Niño-Southern Oscillation (ENSO) teleconnections are the prominent source of interannual variability for the AMS (Vera et al., 2006), as summarized in section 2.4. The response to ENSO events in UKESM1 and HadGEM3 is investigated in this section, first by investigating the mean response to ENSO events and then by analysing possible sources of non-linear teleconnections.

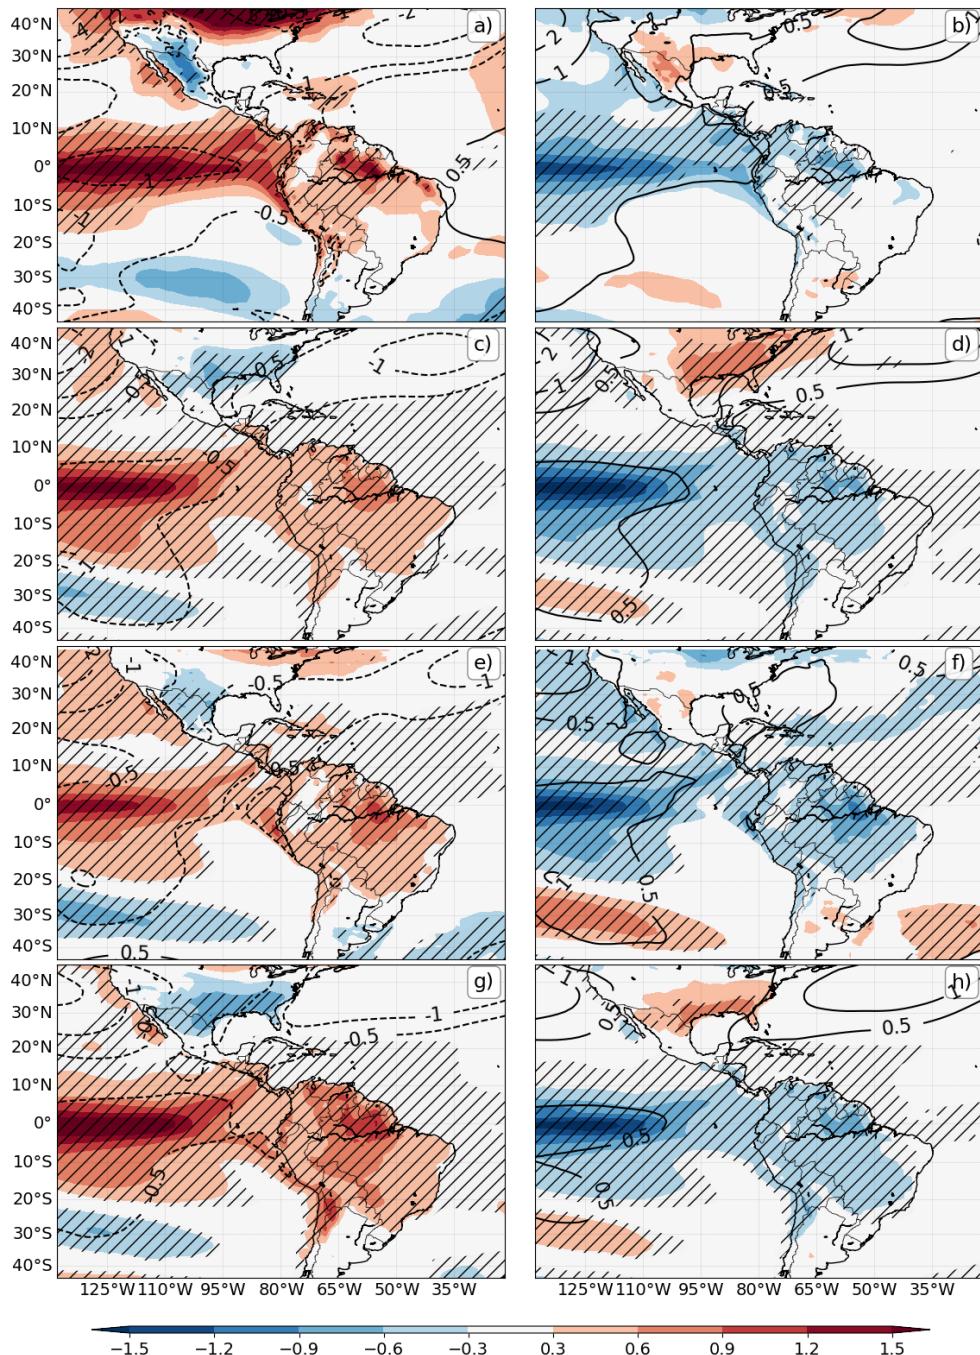

Figure 4.11: DJF Temperature anomalies (colour contours in K) and SLP (line contours in hPa) during (a, c, e, g) El Niño and (b, d, f, h) La Niña events. Results are shown for (a, b) ERA-5, (c, d) UKESM1-hist, (e, f) GC3 N96-pi and (g, h) GC3 N216-pi. The hatched regions denote differences between ENSO phases and the climatological state with significance to the 99% confidence level from a Welch t-test for the temperature field.

4.6.1 Canonical impacts to the AMS

The surface temperature and sea-level pressure (SLP) responses to ENSO events are shown in Figure 4.11 for HadGEM3, UKESM1 and ERA5 data during DJF, the season of strongest impact of ENSO events. The characteristic warm anomaly during El Niño events in the East Pacific Ocean does not extend as far east in the simulations as in the HadSST dataset or ERA5. In turn, the cold anomalies during La Niña events in the Central Pacific are colder in the simulations than in ERA5. The impact to southern North America, i.e., colder (warmer) conditions in southern (northern) North America during El Niño events is relatively well simulated. For example, the simulated and observed impacts to South America, e.g., the cold anomalies during La Niña events in northern South America are well simulated. However, the low resolution simulations show a broader and stronger than observed negative response in southeastern US to El Niño events.

The SLP response in the north Pacific and North America, known as the Pacific North-American pattern (PNA), is linked with a displacement of the subtropical jet affecting the eastward propagation of wave activity that reaches the North Atlantic (e.g. Bayr et al., 2019; Jiménez-Esteve and Domeisen, 2020). During El Niño events, the Aleutian Low is strengthened in ERA5, with a strong SLP anomaly (-4 hPa) off the coast of California. The models show a similar but smaller SLP response in the same region. El Niño events are associated with a negative phase of the North Atlantic Oscillation (NAO), with an opposite response for La Niña events (Fereday et al., 2020). While the models seem to be able to capture this response of the NAO, the simulated response is weaker than observed. A sensible representation of the ENSO-PNA tropospheric teleconnection is important to fully simulate ENSO impacts to North America (Lin, 2015; Bayr et al., 2019) and northeast Brazil (Hastenrath, 2006; Taschetto et al., 2016).

The rainfall anomalies associated with ENSO events (Figure 4.12) show that three regions in the AMS have a significant precipitation response. In southern North America, rainfall increases (decreases) during El Niño (La Niña) events due to the effects of the PNA pattern on the subtropical jet, which influences the frequency and latitude of propagation

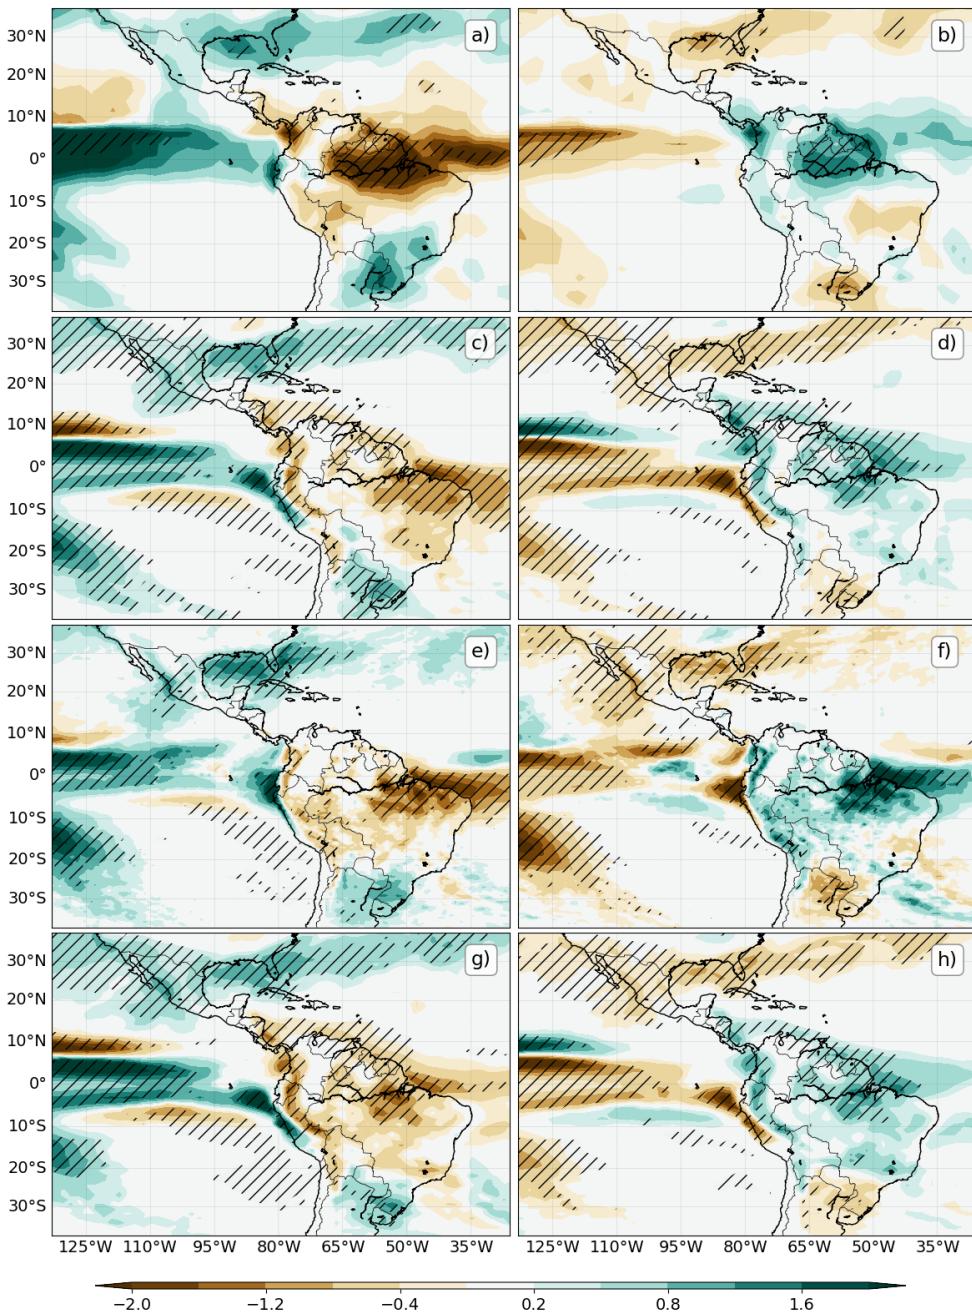

Figure 4.12: As in Figure 4.11 but for the rainfall response [mm day⁻¹] using GPCP as the observational dataset.

of wintertime midlatitude disturbances which are the main source of rainfall in the region during the dry season (Vera et al., 2006; Bayr et al., 2019).

The GPCP dataset (Figure 4.12a, b) shows significant boreal winter rainfall increases in southeastern US and the Gulf of Mexico during El Niño events, and an opposite response to

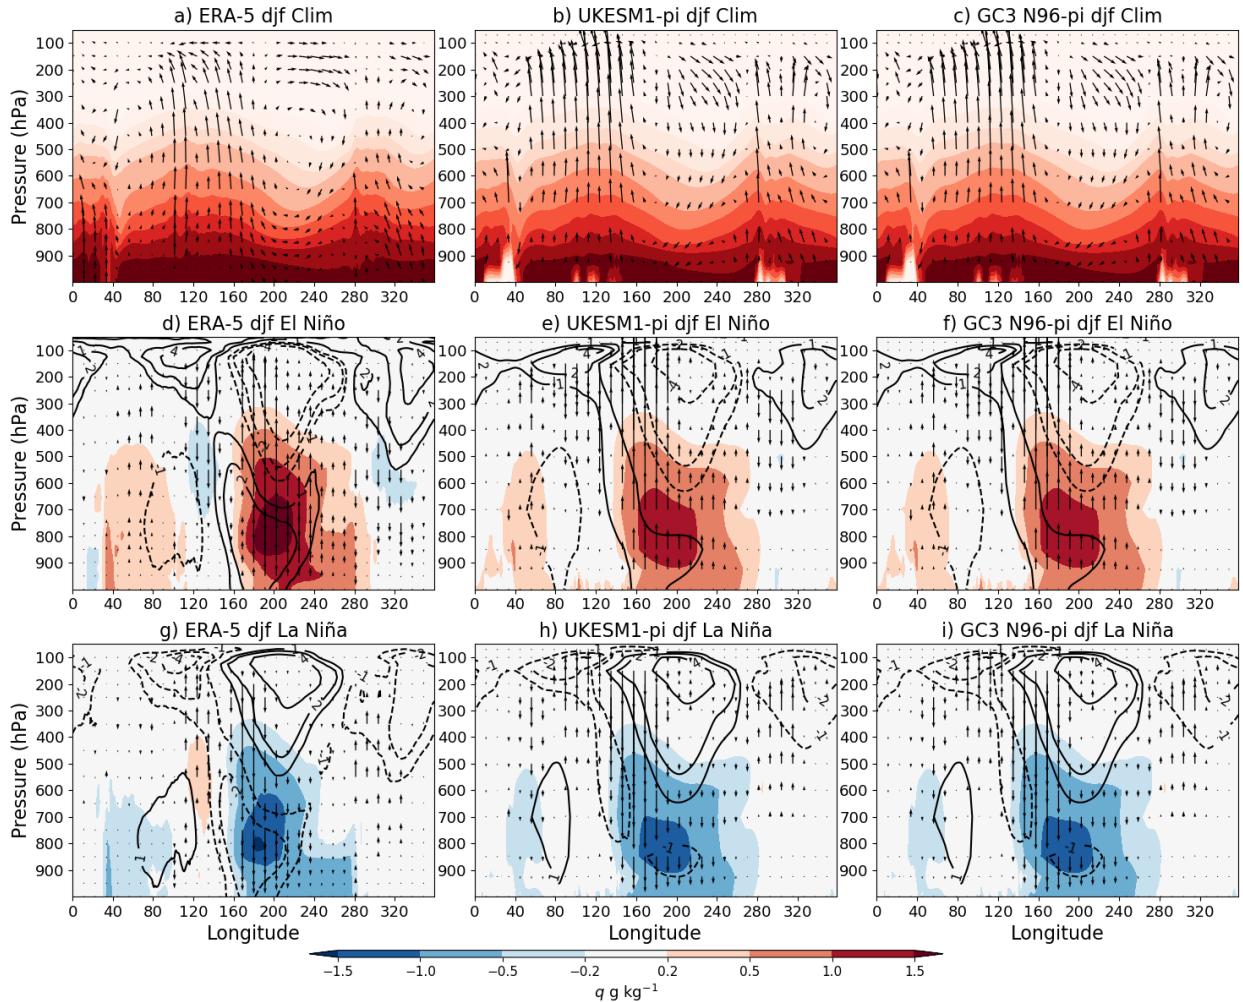

Figure 4.13: DJF Longitude-height Walker circulation (a-c) climatologies and (d-i) anomalies of specific humidity (colour-contours), ω (vectors) and zonal wind (line-contours) during (d-f) El Niño events and (g-i) La Niña events. Results are shown for ERA-5 (left), UKESM-pi (middle) and HadGEM3 N96-pi (right).

La Niña phases. All the simulations reproduce this impact pattern. The models also simulate the observed response in South-Eastern South America (SESA) of positive anomalies during El Niño and negative anomalies during La Niña events. This impact to SESA is due to the subsidence induced by the anomalous Walker circulation which modifies the moisture transport by the SALLJ from the Amazon to SESA (Montini et al., 2019).

The anomalies in the Amazon show the strongest response to ENSO events in the observations. Significant positive (negative) rainfall anomalies during the negative (positive) phase of ENSO in northern South America are observed in GPCP. All the simulations show a very similar and statistically significant response. This teleconnection is due to the coupling

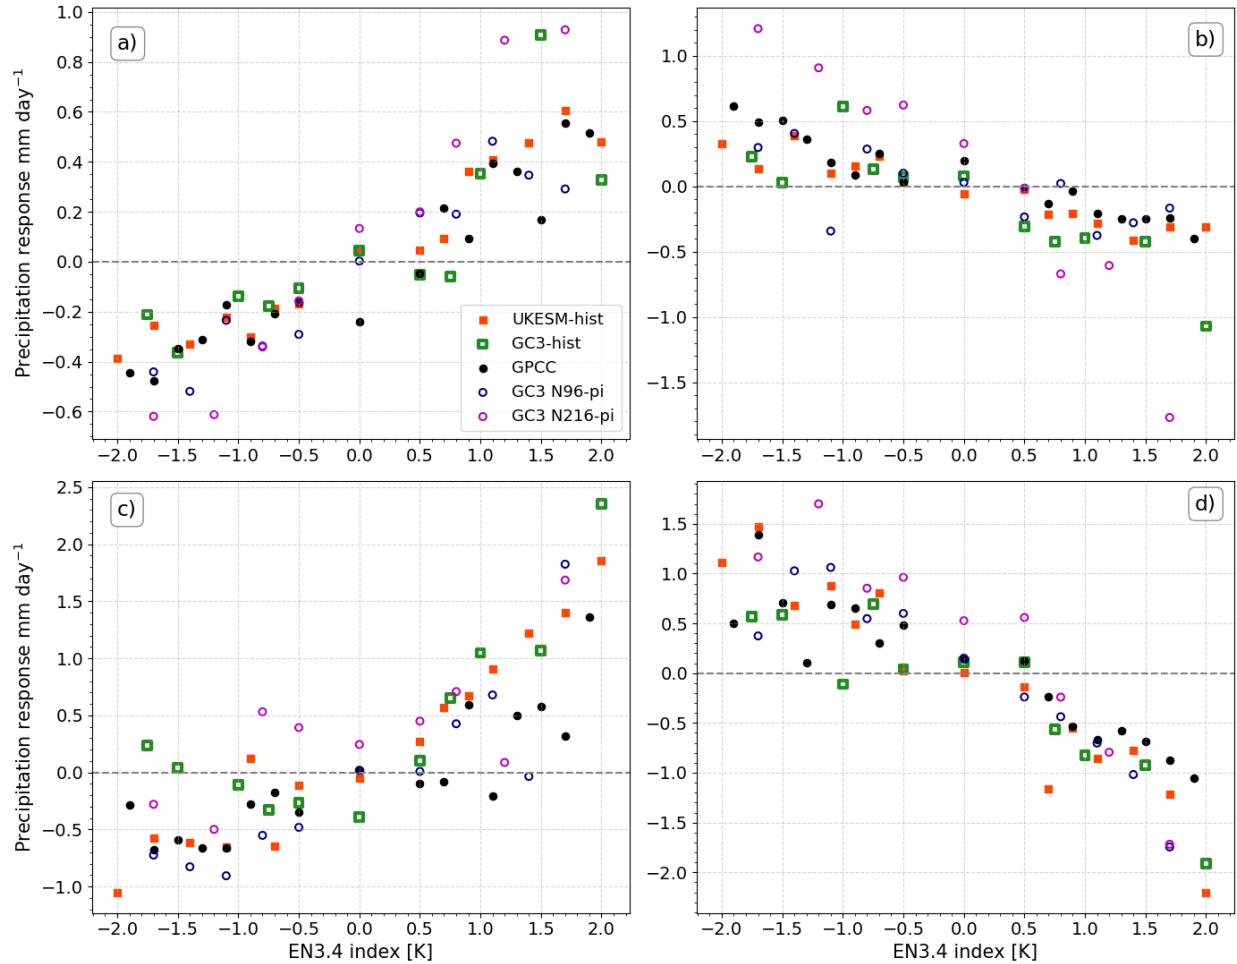

Figure 4.14: Precipitation response [mm day^{-1}] as a function of the El Niño 3.4 index (see text) for (a) southwestern North America [$20\text{-}37^\circ\text{N}, 112\text{-}98^\circ\text{W}$], (b) Central America and southern Mexico [$5\text{-}19^\circ\text{N}, 95\text{-}83^\circ\text{W}$], (c) Sout-Eastern South America [$35\text{-}25^\circ\text{S}, 60\text{-}50^\circ\text{W}$], and (d) the Amazon [$10\text{-}0^\circ\text{S}, 70\text{-}45^\circ\text{W}$]. The observation scatter points are from GPCC in the period of 1940-2013.

of ENSO with the Walker circulation (Vera et al., 2006; Cai et al., 2019), which is illustrated in Figure 4.13, and the effect of the ENSO-PNA teleconnection in the tropical north Atlantic.

The climatological Walker circulation during DJF shows strong ascent in the $100\text{-}160^\circ\text{E}$ and the $280\text{-}310^\circ\text{E}$ regions (Figure 4.13a), which correspond to the maritime continent and South America, respectively. During El Niño events, there is increased specific humidity throughout the lower troposphere in the Central and Eastern Pacific, associated with ascending motions in this region and negative low-level wind anomalies and positive upper-level wind anomalies (Figure 4.13d). In other words, an eastward shift of the Walker circulation. The wind, vertical velocity and specific humidity anomalies are the opposite

during La Niña events, indicative of a stronger Walker circulation shifted west. The models seem to broadly reproduce the observed changes to the Walker circulation during ENSO events (Figure 4.13).

The anomalous descent over equatorial South America is one cause for the drying response seen during El Niño in the Amazon (Marengo et al., 2012; Cai et al., 2020). However, the ENSO-PNA teleconnection decreases in the tropical north Atlantic (Fig. 4.11), inducing a warming of the SSTs and a delay in the southward migration of the Atlantic ITCZ (Andreoli et al., 2012; Jimenez et al., 2021). Even though the models are able to simulate the ENSO-PNA SLP effect, this effect is slightly weaker than observed, particularly for El Niño events.

Figure 4.14 shows the observed and simulated precipitation responses in four regions of the AMS binned by the magnitude of ENSO events, measured by the EN3.4 index. This figure aims to show the degree of linearity of ENSO teleconnections to the AMS, i.e., a precipitation response that linearly scales with the magnitude of the ENSO event. Both simulated and observed responses show degrees of non-linearity in various regions. For example, the precipitation response in the Amazon to La Niña events in observations appears to be relatively constant regardless of the strength of the event whereas in GC3 N96-pi the strongest La Niña events do not produce the strongest precipitation response over this region. This evidence suggests that for some regions there are varying degrees of non-linearity of ENSO impacts.

4.6.2 The role of ENSO flavours

As described in section 2.4, not all ENSO events are observed with the same SST pattern in the Pacific Ocean. These different SST patterns are considered to be a source of non-linearity of ENSO impacts over South America (Sulca et al., 2018; Cai et al., 2020). Figure 4.15 shows that both UKESM1 and GC3 reasonably simulate the observed SST patterns associated with EP and CP El Niño events, although the CP SST patterns in the simulations spread further to the east than the HadSST dataset. The simulations are also able to replicate very broadly the observed differences in the frequency of each event as CP La Niña events are more frequent than EP La Niña events, while the opposite is true for El Niño events.

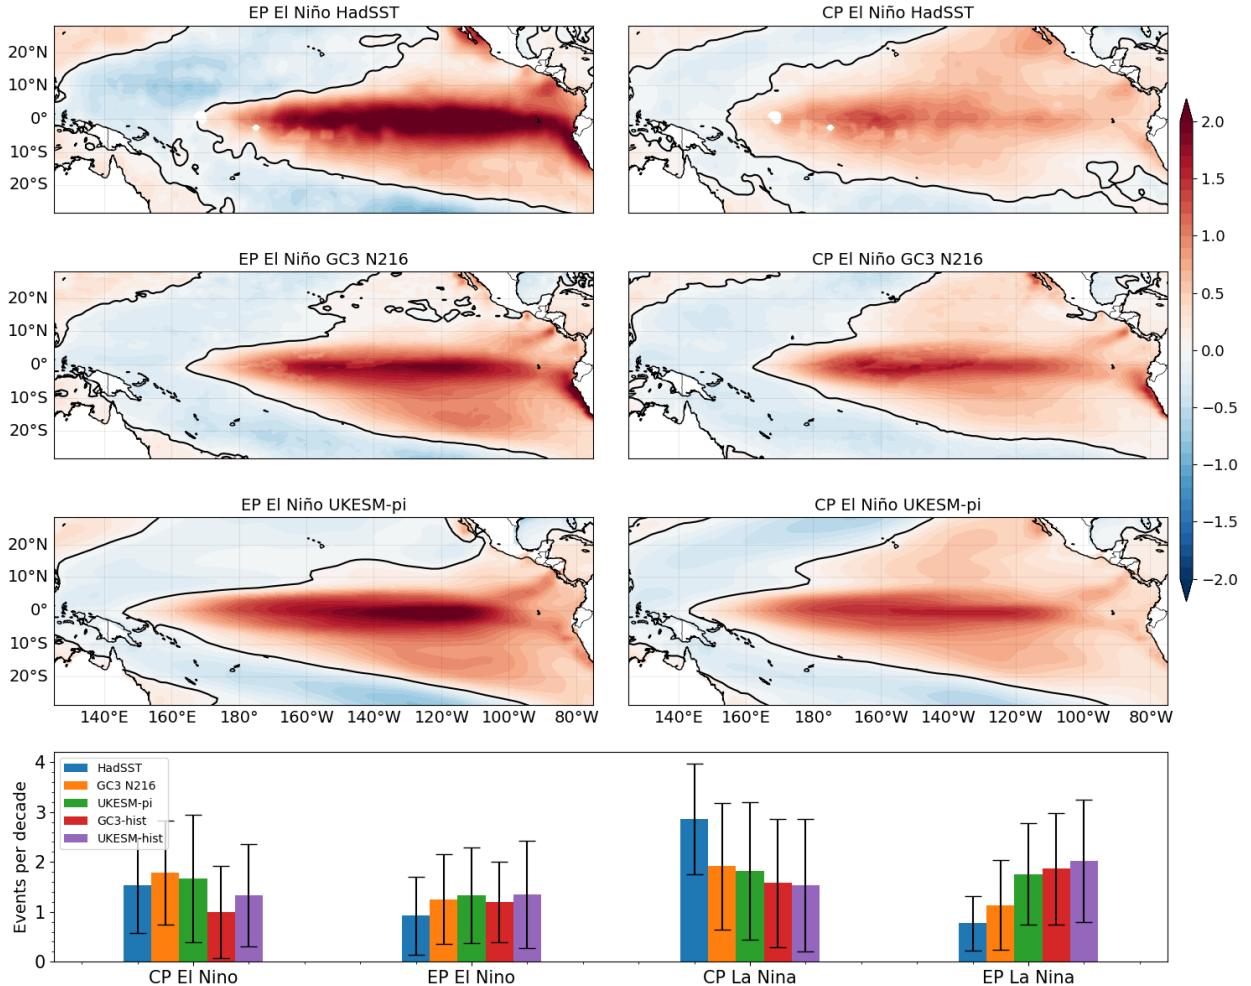

Figure 4.15: SST anomalies [K] for East Pacific (EP) and Central Pacific El Niño events in HadSST, GC3 N216 and UKESM piControl. In the bottom panel, the frequency of events per decade (with standard deviation as error bar) is shown for HadSST and the simulations used in this study.

Furthermore, Figure 4.16 compares the precipitation anomalies for each type of ENSO event in observations with three simulations: GC3 N96-pi, GC3 N216-pi and GC3-amip. The observed precipitation response in the GPCC dataset to EP La Niña over equatorial South America is not significant and is smaller than the strong positive response to CP La Niña events in the same region. However, the simulated response in GC3 N96-pi and GC3 N216 during La Niña events appears to be more independent of the type of event. In contrast, the GC3-amip simulations shows different magnitudes of responses to different types of La Niña events, in particular a positive, and significant, anomaly for CP La Niña events in the Amazon and weaker but not significant anomalies during EP events, which agrees with observations.

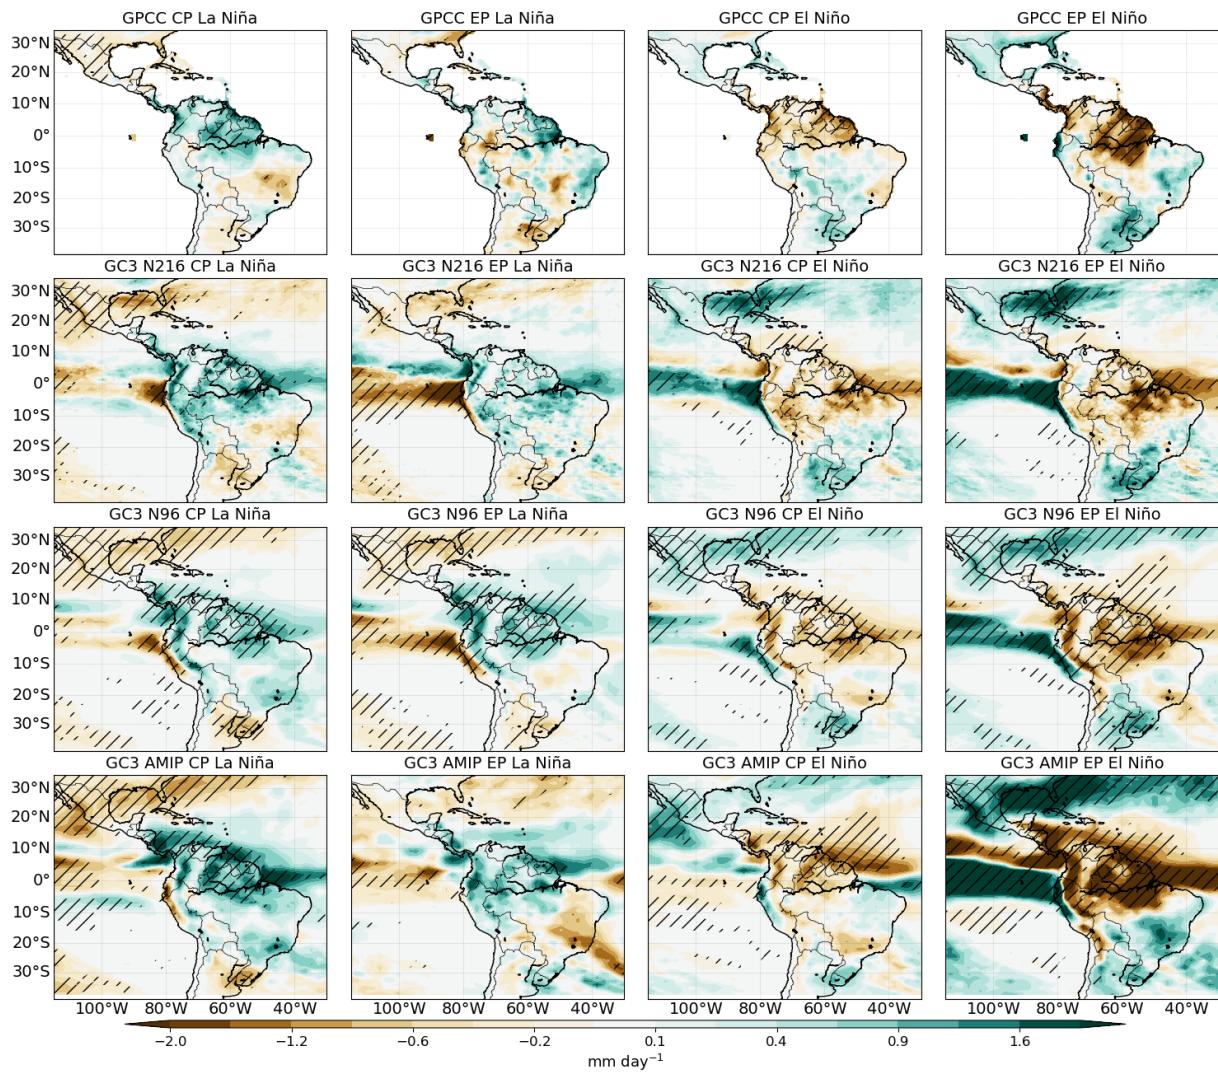

Figure 4.16: Precipitation anomalies in GPCC 1940-2013, GC3 N216-pi, GC3 N96-pi and GC3 AMIP for the four different types of ENSO events, as defined by Cai et al. (2020). Statistically significant anomalies (95% confidence level) are hatched.

The observed response to El Niño events in GPCC is also dependent on the type of event. EP El Niño events show significant negative anomalies over the Amazon and positive anomalies over SESA whereas CP events only show significant anomalies (-1 mm day^{-1}) over northeastern South America. While the coupled models (GC3 N96-pi and GC3 N216) show a stronger response to EP El Niño events than to CP events. In contrast, the response in GC3-amip agrees with observations, as stronger negative responses to EP El Niño events are observed in the Amazon compared to CP events in which the response is much weaker and is only significant in northeastern South America. In other words, GC3-amip agrees

well with the observed non-linear impacts whereas the teleconnections in the coupled models do not seem to depend so strongly on the type of ENSO event.

4.6.3 A possible influence of the QBO on tropical ENSO teleconnections

Section 2.5 discusses the observational and modelling evidence that suggest a role for the stratospheric quasi-biennial oscillation (QBO) in modulating the determine interannual variability of the Walker circulation and monsoons (Giorgetta et al., 1999; Collimore et al., 2003; Liess and Geller, 2012). This section evaluates whether the simulations analysed in this chapter, as well as observations, show signs of an influence of the QBO on the AMS. In particular, the analysis aims to understand whether the QBO may be a source of non-linearity for the teleconnections of ENSO associated with deep convection and the Walker circulation.

Composites of the precipitation response to La Niña (LN) events in Figure 4.17 show that the phase of the QBO may determine the strength and location of the impact. While the precipitation difference in the western Pacific is relatively similar during QBOe than during QBOw in observations and simulations, the teleconnections to Australia, South America and the maritime continent are notably different depending on the QBO phase. In the GPCP dataset, the composite difference QBOe-QBOw during LN events suggests that the characteristic positive precipitation response during LN events in the Amazon, is largely associated with QBOw phases, whereas LN events during QBOe appear to have little effect over South America. A similar result is obtained for GC3 N96-pi.

These precipitation responses are further investigated by changes in the overturning circulation (Figure 4.18). As depicted in Figure 4.13, La Niña events are associated with a westward shift in the Walker circulation with a strengthening of the low-level easterlies in the Pacific Ocean. Figure 4.18 shows that during LN the tropical troposphere cools and the UTLS region in the Central Pacific warms. The zonal wind anomalies in the upper-troposphere associated with LN events show different patterns and strengths during QBOw than during QBOe. The mean teleconnections during LN show positive zonal wind anomalies in the upper troposphere of the Pacific Ocean, but these anomalies are stronger

during QBOe than during QBOw in ERA5 and the two simulations shown. In ERA5, most of the upper troposphere shows positive zonal wind differences in the QBOe-QBOw panel.

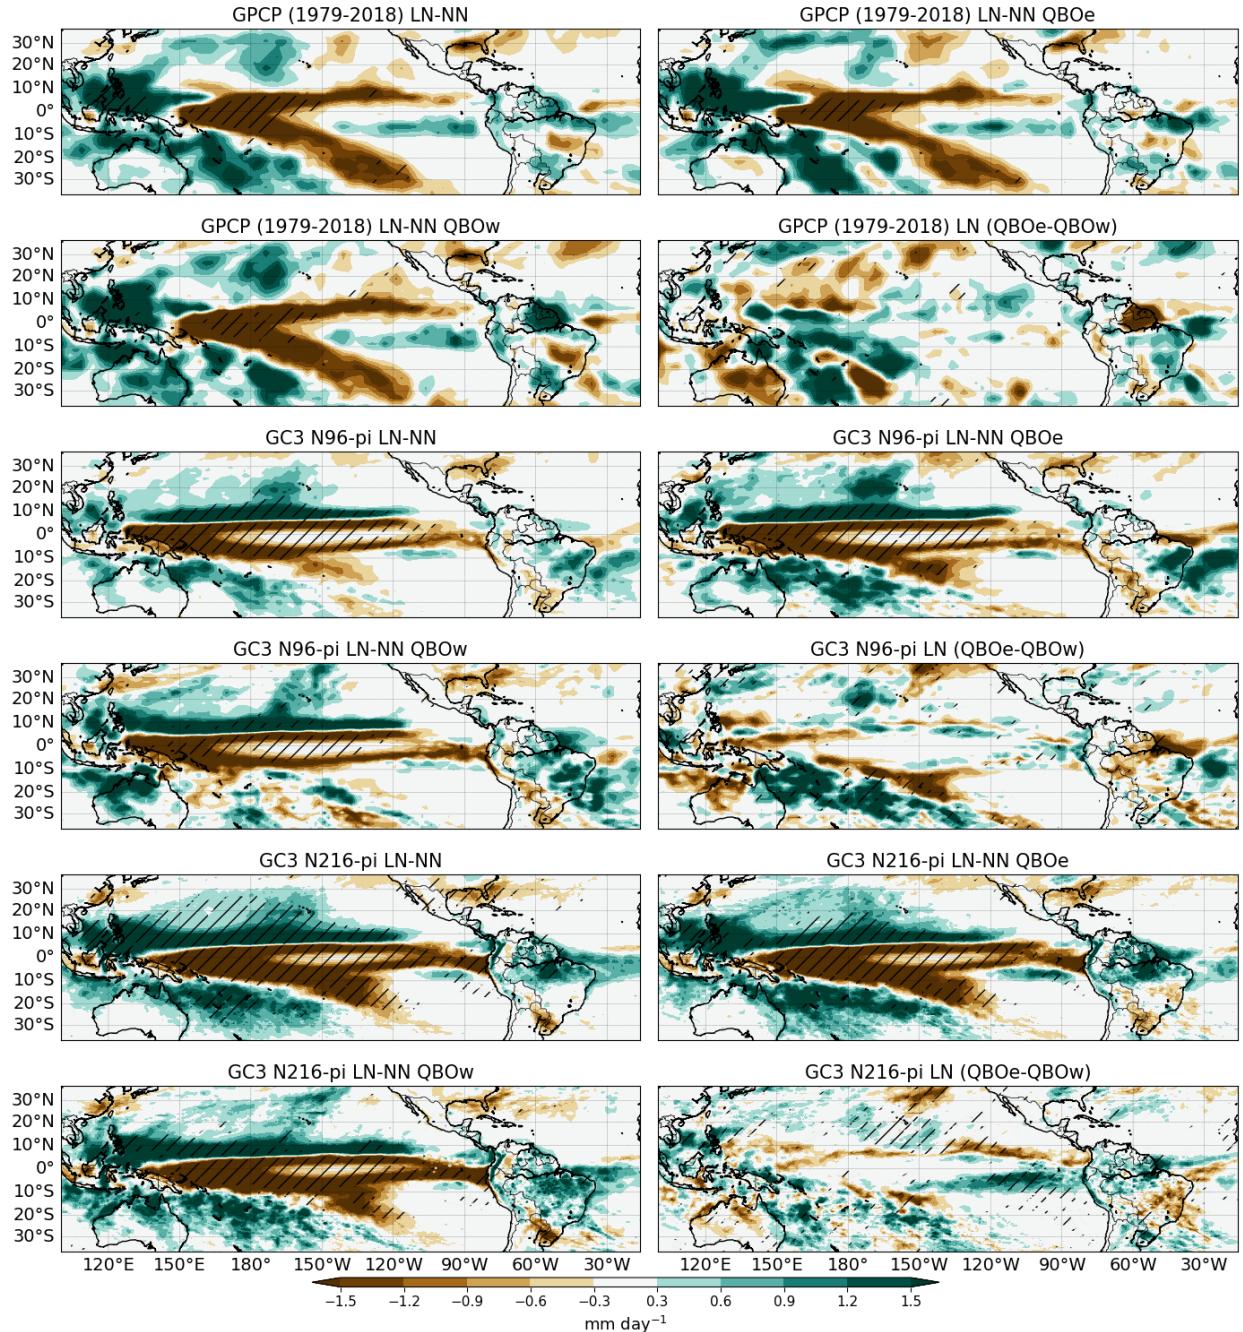

Figure 4.17: Composite precipitation differences during JFMA in GPCP (1979-2018), GC3 N216-pi and GC3 N96-pi between (top) La Niña and Neutral ENSO conditions. The two middle panels show a subset of the top panel, by separating the La Niña composite based on the phase of the QBO. The lower panel shows the differences QBO E-W during La Niña periods. Statistically significant anomalies (95% confidence level) are hatched.

The effect of LN over ascending and descending motions is also affected by the QBO phase (Fig. 4.18). In ERA5 and the simulations, the anomalous ascent observed in South America during LN events is mostly associated with QBOw, whereas only small anomalous ascent is observed during QBOe. However, ERA5 disagrees with the simulations in the western Pacific region ($140\text{-}180^\circ\text{E}$), as the simulations suggest larger anomalous descent during QBOe than during QBOw, whereas in ERA5 these descending anomalies are larger during QBOw.

The effect of the QBO during the positive and the neutral phases of ENSO were also evaluated but these results are not shown because, although tentative suggestions were

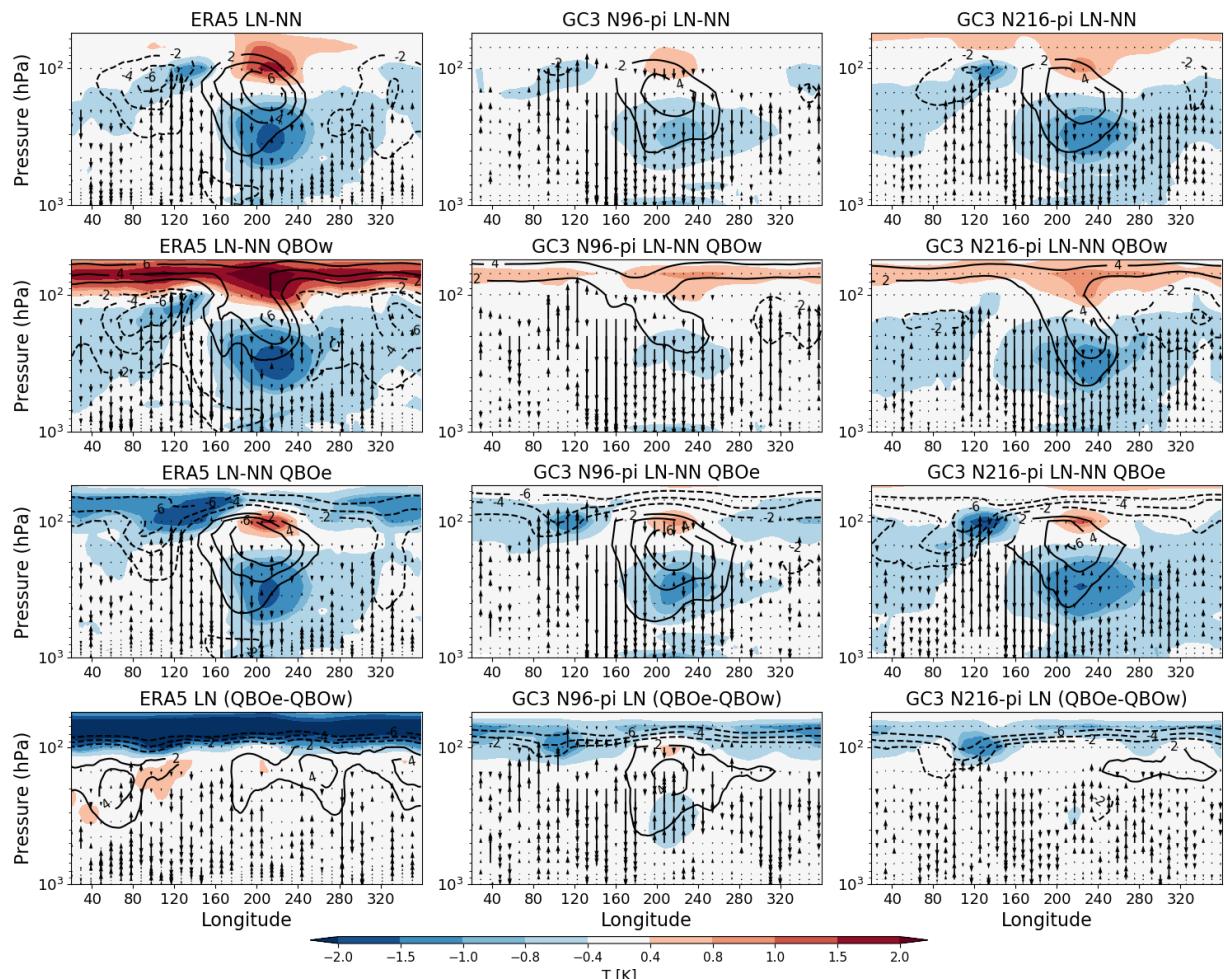

Figure 4.18: Longitude-height differences (JFMA) of equatorial ($10\text{S-}10\text{N}$) air temperature (color shading), zonal wind (contours) and vertical velocity (ω - vectors). The differences shown from top to bottom are between all La Niña (LN) periods and Neutral conditions (NN), between LN and NN during QBOw, LN-NN during QBOe, and the difference between LN events on different QBO phases (LN QBOe-QBOw).

found that the QBO may play a role during these other phases of ENSO, there was little agreement between the models and ERA5/observations. Model biases in the representation of the QBO, specially the temperature signal associated with circulation of the QBO, most clearly seen in the bottom panels of Figure 4.18, in addition to short record of the reanalysis evidence (ERA5) or presented in this chapter warrants both caution and future work.

4.7 Summary and discussion

This chapter assessed the contributions to CMIP6 from the models HadGEM3 and UKESM1 for their representation of the AMS climate and associated large-scale tropical circulation. These CMIP6 experiments allow the comparison of the effect of including Earth System processes or increasing resolution for representing regional monsoon rainfall. A schematic in Figure 4.19 shows the primary components of the AMS climate and summarises the main biases found in these simulations and this chapter.

Rainfall in the North American Monsoon was particularly well simulated by the models. The seasonal cycle, peak monsoon rainfall rates and timings of monsoon onset and retreat in the simulations agreed well with TRMM. The historical experiments overestimate the mean temperature in most of the Americas by 1.5 K, but particularly in boreal summer in southwestern North America (+4 K). Despite this warm bias, the seasonal cycles of precipitation and surface temperature are well represented by these models. These results suggest model improvement of the simulation of the North American Monsoon from previous versions of the MOHC models (Arritt et al., 2000), and most of the model cohorts of CMIP3 and CMIP5 (Geil et al., 2013). However, these models continue to show biases during monsoon retreat as rainfall does not decrease as sharply as in observations after mid-September, which suggests a continued bias in the winter-time precipitation associated with cold-fronts (Adams and Comrie, 1997).

The Midsummer Drought (MSD) of southern Mexico and Central America is a regional feature of precipitation that most CMIP5 models do not capture (Ryu and Hayhoe, 2014). The MSD in UKESM1 and HadGEM3 is relatively well represented. However, the experiments analysed in this chapter simulate a wetter-than-observed first peak of

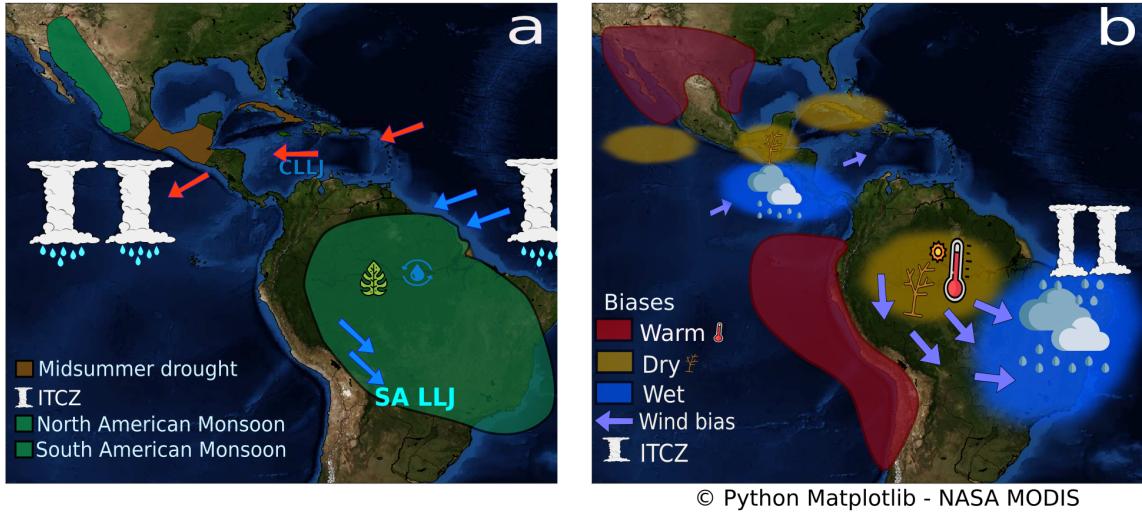

Figure 4.19: Schematics of (a) the main features in the AMS and (b) the main biases in UKESM1 and HadGEM3. In (a) the boreal summer easterlies (red) and austral summer circulation (blue) are shown with the Caribbean and **South American** Low-level Jets (CLLJ and **SALLJ**, respectively). In (b) the biases are shown for the respective northern and southern Hemisphere summers. The ITCZ bias in (b) refers to the southward displacement bias of the Atlantic ITCZ in the simulations.

precipitation and a drier MSD period, therefore simulating a larger difference between the first peak and the dry period. Rainfall during the first peak has been too wet in these models since CMIP3, suggesting a persistent wet bias in this region, likely associated with the bias in East Pacific ITCZ also shown in this chapter and in recent studies (Ryu and Hayhoe, 2014; Mulcahy et al., 2018). In contrast, the so-called second peak of precipitation, observed in late August, is simulated in close agreement with TRMM, except in the GC3 AMIP experiment, which has a wet bias of 2 mm day^{-1} at this stage. The relative skill of UKESM1 and HadGEM to simulate this bimodal regime of precipitation makes these simulations ideal to understand the mechanisms underpinning the MSD, an outstanding question (see Section 2.3).

The East Pacific ITCZ migration and position is relatively well represented by the models (Figs. 4.4 and 4.5). However, the models overestimate the boreal summer rainfall near the coast of Central America (Figure 4.9). These biases are associated with an easterly wind bias at low levels, suggesting a bias in the flow from the Caribbean Sea into the Eastern Pacific. The simulations also show that the position of the Atlantic ITCZ is biased south of the observed ITCZ during boreal winter (Figure 4.5), particularly in the low-resolution coupled configuration.

The dry Amazon bias persists in these CMIP6 experiments. The simulations show a warm bias (+2 K) during austral spring and summer in the Amazon, a bias that exists since CMIP5 (Jones and Carvalho, 2013), and a colder than observed southeastern Brazil. These biases were linked with decreased cloud cover and less rainfall over the Amazon and more convective clouds and rainfall in southeastern Brazil (Figures 4.8 and 4.10). The low cloud cover, warm and dry Amazon biases are intertwined with the low-level circulation from the Atlantic into the South American continent. The biases in the circulation during austral summer were observed as a northerly flow anomaly over the central and southern Amazon, a feature that has been associated with a stronger moisture transport away from the Amazon (Marengo et al., 2012; Jones and Carvalho, 2018).

During the period of maximum rainfall rates in February, the simulations overestimate rainfall by 3 mm day⁻¹ in southeastern Brazil and underestimate rainfall in the Amazon by a similar rate. The historical experiments show a small drying response to historical forcing in the Amazon but this response is much smaller than the magnitude of the biases, increasing the uncertainty in the response. The AMIP simulation improved the representation of the Atlantic ITCZ and the precipitation, cloud cover and temperature biases over the South American Monsoon. The improvement in the circulation and precipitation biases in the AMIP simulation suggest that the origin of the dry Amazon bias are the biases in the Atlantic SSTs.

The canonical ENSO teleconnections of temperature, SLP and precipitation in the AMS are well represented in these models. The simulated spatial patterns and strength of the positive (negative) precipitation anomalies observed in northern Mexico and South-Eastern South America during El Niño (La Niña) agree well with observations and reanalysis. Similarly, the teleconnection to the Amazon is well represented for both phases of ENSO, despite the biases in the mean state of the South American monsoon discussed above.

ENSO teleconnections in these simulations were found to be approximately linear, i.e., the precipitation response is linearly related to the magnitude of the SST anomaly in the EN3.4 region. These experiments also show symmetric teleconnections as positive and negative phases produce the opposite and equivalent precipitation response in the AMS. In contrast to observations and the GC3 AMIP simulation, the precipitation response in the coupled models appears to be independent of the type or flavour of ENSO events, i.e.,

between Central and East Pacific events. The fact that these models show a reasonable representation of ENSO diversity in SST patterns but the models do not replicate the observed non-linear dependence to ENSO events warrants further analysis.

The QBO appears to be a source of non-linearity for ENSO teleconnections to the Amazon. La Niña teleconnections in the Amazon are characterized by a stronger ascent associated with a stronger Walker circulation. The La Niña teleconnection pattern occurs primarily during the westerly phase of the QBO, whereas the teleconnection during the easterly phase is much weaker and barely different from the climatological mean-state. Whether the stratospheric QBO modulates the main source of interannual variability (ENSO events) for monsoon rainfall in the Amazon merits a separate chapter of this thesis (Chapter 7).

The main biases (Fig. 4.19) in these experiments are generally smaller in the medium-resolution GC3 N216 compared to the low-resolution experiments (N96), which suggests improved model performance with increased horizontal resolution. In contrast, including Earth System processes in the UM model only affects the surface temperature response to historical forcing and not the dynamical biases that drive the precipitation and ITCZ biases. In general, UKESM1-hist shows a stronger temperature response to forcing than GC3 N96-hist, as UKESM1 has been reported to have a greater climate sensitivity than GC3 N96 (Andrews et al., 2019a; Sellar et al., 2019).

The improvement in the medium-resolution simulation compared to the low-resolution simulations may be attributed to the improved dynamics of the ocean and the atmosphere. For example, the Atlantic ITCZ biases have been shown to be directly affected by processes in the convective scheme (Bellucci et al., 2010), such as the treatment of entrainment and moisture-cloud feedbacks (Oueslati and Bellon, 2013; Li and Xie, 2014). The resolution of the ocean model has been shown to impact the eddy heat flux parametrisation and the associated heat uptake and transport of the ocean (Kuhlbrodt et al., 2018). The improvement in the Atlantic SSTs and ITCZ and the associated dynamics in GC3 N216-pi also improves the associated circulation biases and moisture transport in the South American Monsoon. In other words, the oceanic resolution may play an important role in the cross-equatorial heat and moisture transport which largely control the SST gradients over the equatorial Atlantic.

The SST biases in the Atlantic are likely the dominant factor to accurately simulate the spatial distribution of rainfall in South America.

5

A wavelet transform method to determine monsoon onset and retreat

This chapter describes a new method to determine monsoon onset and retreat timings using wavelet transform methodology applied to precipitation time-series at the pentad scale. The use of the method is illustrated for the North American Monsoon and the Indian Monsoon using four different precipitation datasets and climate model output. An extension of the method is used to identify the timings and strength of the Midsummer Drought of southern Mexico, Central America and the Caribbean. This chapter is based on the publication: García-Franco et al. (2021) in which all the analysis was performed by the lead author.

5.1 Introduction

The timing and strength of the rainy season are key aspects of the climate of monsoon regions as the onset or start and the retreat or end of the monsoon rainfall greatly influences sectors such as agriculture (Sultan et al., 2005; Gadgil and Rupa Kumar, 2006; Jain et al., 2015; Harvey et al., 2018) and water management (Turner and Annamalai, 2012; Bussmann et al., 2016). Scientific and societal motivation has led climate and weather research to objectively determine onset and retreat dates for purposes such as the characterisation of variability

and trends, and forecasting (e.g. Kitoh and Uchiyama, 2006; Cook and Buckley, 2009; Lucas-Picher et al., 2011; Nieto-Ferreira and Rickenbach, 2011; Htway and Matsumoto, 2011).

For this reason, a wide range of methods exist to diagnose the onset and retreat dates from a number of variables and datasets. Bombardi et al. (2020) provide a recent review of these methods and highlight the technical differences and purposes of each. Methods can be divided into those that evaluate monsoon onset and retreat on a regional scale (e.g. Webster and Yang, 1992; Fasullo and Webster, 2003; Garcia and Kayano, 2013) or at a local or grid-box scale (e.g. Liebmann and Marengo, 2001; Cook and Buckley, 2009).

Threshold methods are the most commonly used local-scale methods that typically diagnose onset and retreat from a precipitation time-series (Bombardi et al., 2020). These methods evaluate the accumulated (Liebmann and Marengo, 2001) or daily/pentad-mean rainfall rates (Geil et al., 2013) and determine the onset and retreat dates when the time-series exceeds or falls below a pre-defined value (threshold) for a given amount of time (persistence). The persistence parameter aims to decrease the effect of the noise of precipitation time series in the calculation. The threshold parameter can be a statistical measure of the seasonal cycle such as the total annual mean rainfall (Arias et al., 2012) or tuned to a specific dataset (e.g. Geil et al., 2013).

In other words, for a given purpose each threshold method is tailored to a monsoon region using a specific dataset and a specific variable. This characteristic of the threshold methods poses various shortcomings. Firstly, practical shortcomings of the threshold methods, particularly rigid thresholds, include false hits (Moron and Robertson, 2014) or some years not meeting the threshold and persistence criteria (Arias et al., 2012) requiring further relaxation of the parameters. Secondly, given that threshold methods are tailored to a specific dataset in a given region, statistical corrections are needed to implement the same threshold method in a different dataset or in another region.

CMIP assessments of monsoon onset and retreat typically use precipitation threshold methods due to the lack of data with high temporal or vertical resolution from all models to estimate vertically integrated quantities required for some methods (e.g. Geil et al., 2013; Zou and Zhou, 2015; Ha et al., 2020). Threshold methods have multiple shortcomings for CMIP assessments as the persistence and threshold parameters are tuned for observations

with a specific seasonal cycle but models have a range of biases in the seasonality, magnitude and spatial distribution of rainfall (Pascale et al., 2019; García-Franco et al., 2020). The use of pre-defined threshold values may also not be suitable to compare different model experiments with changes in forcing where the climatological mean rainfall or the seasonal cycle may change within the model run. These shortcomings are relevant because a proper diagnosis of the seasonal cycle in CMIP assessments is key to understand and diagnose current and future changes to monsoon seasonality as a result of greenhouse forcing (Zhou et al., 2016; Wang et al., 2017).

The objective diagnosis of shorter time-scale rainfall variability, such as bimodal regimes and active and break phases of a monsoon, also requires methods that can separate relatively drier and wetter periods within the rainy season. For example, for the MSD of Central America and the Caribbean (section 2.3) the objective determination of the strength, spatial distribution and robustness of the bimodal signals is not straightforward. For example, the global method used in Bombardi et al. (2020) fails to diagnose the region of southern Mexico, Central America and the Caribbean as a bi-modal regime.

The majority of existing methods to diagnose bimodal signals in the MSD region use geometric or statistical measures of the monthly-mean rainfall that measure the difference between the months of maximum rainfall and the drier months. However, this approach fails to capture the shorter-scale changes that have been shown to occur in both observations and model data, as the MSD does not start or end exactly on given calendar months (Magaña et al., 1999; García-Franco et al., 2020). Zhao and Zhang (2021) review and compare several methods to detect and measure the MSD, finding that using monthly-mean data and prior assumptions of the dates of the first and second peaks can lead to errors.

In short, multiple methods exist to diagnose monsoon onset and retreat as well as bimodal signals, each with various parameters fit for different purposes, but these methods present shortcomings for studies that compare results from multiple datasets or investigate model experiments where the climatological rainfall and the seasonal cycle are non-stationary. Both the objective determination of monsoon onset and retreat and the timings of bimodal regimes require a method that can analyse temporal changes to precipitation on several scales and that can be used on any gridded dataset.

The purpose of this chapter is then to present an objective approach that is more portable across datasets, regions, less prone to false hits and robust for various purposes. This chapter introduces a wavelet transform method to determine monsoon onset and retreat dates using pentad-mean precipitation time series. Wavelet algorithms have been extensively used in atmospheric research for multiple purposes, such as the detection of the boundary layer height (e.g. Brooks, 2003), as well as to analyse time-frequency features of a signal (e.g. Whitcher et al., 2000; Dimdore-Miles et al., 2021). In fact, Allen and Mapes (2017) used wavelet analysis to determine monsoon onset and retreat using daily OLR data.

The remainder of this chapter is organised as follows: section 2 describes the methods and datasets. Section 3 shows the results of applying the method to the Indian and North American Monsoons and the MSD. [The method is illustrated in the North American Monsoon to compare the proposed method to threshold methods of precipitation, and for the Indian Monsoon region to compare the method to a well known index of the regional moisture transport, which is a more physically-based method.](#) In this way, we test the wavelet transform method against different existing and commonly-used methods. Section 4 summarises the method and discusses the results.

5.2 Data

5.2.1 Precipitation datasets and reanalysis data

This chapter uses three gridded precipitation datasets described in chapter 3: the TRMM v7 3B42, the CHIRPS, and the CMAP datasets. These three precipitation datasets are merged products, TRMM and CMAP mainly use microwave satellite measurements complemented by several other sensors and calibrated with rain-gauge data whereas CHIRPS uses several products from TRMM, as well as high-resolution station data. These datasets also differ in their end-product horizontal resolutions.

The precipitation output from the latest ECMWF reanalysis, ERA5, is used, which has been shown to exhibit a relatively good representation of the temporal characteristics of rainfall in the AMS in chapter 4. Other variables from ERA5 used to diagnose changes

to the circulation associated with monsoon onset were daily-mean geopotential height at 500 hPa and wind speed (\vec{u}) at several vertical levels.

5.2.2 Model data

Daily precipitation data from the CMIP6 archive are used and retrieved from: <https://esgf-index1.ceda.ac.uk/projects/cmip6-ceda/>, to illustrate the method using standard climate model output. In particular, we use results from the piControl and historical simulations of HadGEM3 GC3.1 and UKESM1, described in chapter 3. The daily precipitation data were converted to pentad-scales.

5.3 The wavelet transform method

Wavelets are band-limited wave-like functions with specific mathematical properties that include finite energy and zero-mean (Whitcher et al., 2000; Addison, 2017). The wavelet function is defined using two parameters, a dilation (a width or temporal scale) and a translation (centroid in time/space).

Wavelet transforms are the result of the inner product (convolution) of a wavelet function with a time series or a signal (Addison, 2017). The wavelet transform (WT) can be thought of as a local comparison between the wavelet function and the observed signal for different frequencies. The information provided by a WT largely depends on the characteristics of the wavelet function, such that different wavelet functions are used for different purposes (Addison, 2017). For the purpose of finding the onset and retreat dates, the wavelet-based on the Haar function is useful as this wavelet finds sudden changes in a signal, acting as a time filter of the data (Addison, 2017; Brooks, 2003). The Haar wavelet is defined as the non-continuous piece-wise function:

$$\psi\left(\frac{t-b}{a}\right) = \begin{cases} 1 & b \leq t < b + \frac{a}{2} \\ -1 & b - \frac{a}{2} \leq t < b \\ 0 & elsewhere, \end{cases} \quad (5.1)$$

where a is the dilation coefficient, b is the centre of the wavelet or the translation coefficient and t is the time coordinate.

The wavelet covariant transform is then the inner product of the Haar wavelet with a timeseries (Brooks, 2003), as follows:

$$W_f(a, b) = \frac{1}{a} \int_{t_i}^{t_f} pr(t) \psi\left(\frac{t-b}{a}\right) dt, \quad (5.2)$$

where $pr(t)$ is a time series of precipitation, either on daily or pentad scales and $W_f(a, b)$ is the matrix of the covariant transform and t_i and t_f are the start and end time-points. No statistical treatment, normalization or anomaly, *a priori*, is calculated on the precipitation time series $pr(t)$ so the units of W_f are the same as the precipitation time series (e.g. mm d⁻¹).

Monsoon timings can be observed as sharp changes to precipitation, i.e., rainfall sharply increases at onset and sharply decreases at retreat. However, measuring these changes can be difficult since precipitation time series are typically noisy. The Haar wavelet is useful in these cases for signal detection since the WT is interpreted as gradients across different temporal scales and can smooth out the high-frequency variability using sufficiently large dilation scales. In other words, the wavelet covariant transform ($W_f(a, b)$) filters the time series $pr(t)$ using a temporal scaling of a , or measures gradients on a scale a for each time-step (b).

Figure 5.1 shows the Haar wavelet and one year of observed precipitation in the North American Monsoon from the CMAP dataset. Figure 5.1a illustrates how the wavelet function compares the observed signal in the interval $b \leq t < b + \frac{a}{2}$ with the values of the signal in the interval $b - \frac{a}{2} \leq t < b$ where b in this case is a pentad time step. The WT coefficient for dilation $a = 20$ pentads at the translation of $b = 35$, i.e., pentad 35, is a measure of the precipitation difference between the sum of the observed rainfall 10 pentads after pentad 35 and the sum of the observed rainfall 10 pentads before pentad 35 as illustrated in Figure 5.1b.

Figure 5.2 shows an example of the WT application using the observed climatological precipitation in the North American Monsoon in four different precipitation datasets. The mean climatological rainfall rates (upper panel) differ in their peak summer rainfall rates but qualitatively show similarities in the start and end dates of the rainy season. The WT coefficients ($W_f(a, b)$ in the middle panel) for a small dilation $a = 4$ are relatively noisy but show a clear maximum and minimum that correspond well with the maximum and minimum of longer dilations ($a = 14, 20$). The sum of these four coefficients at each

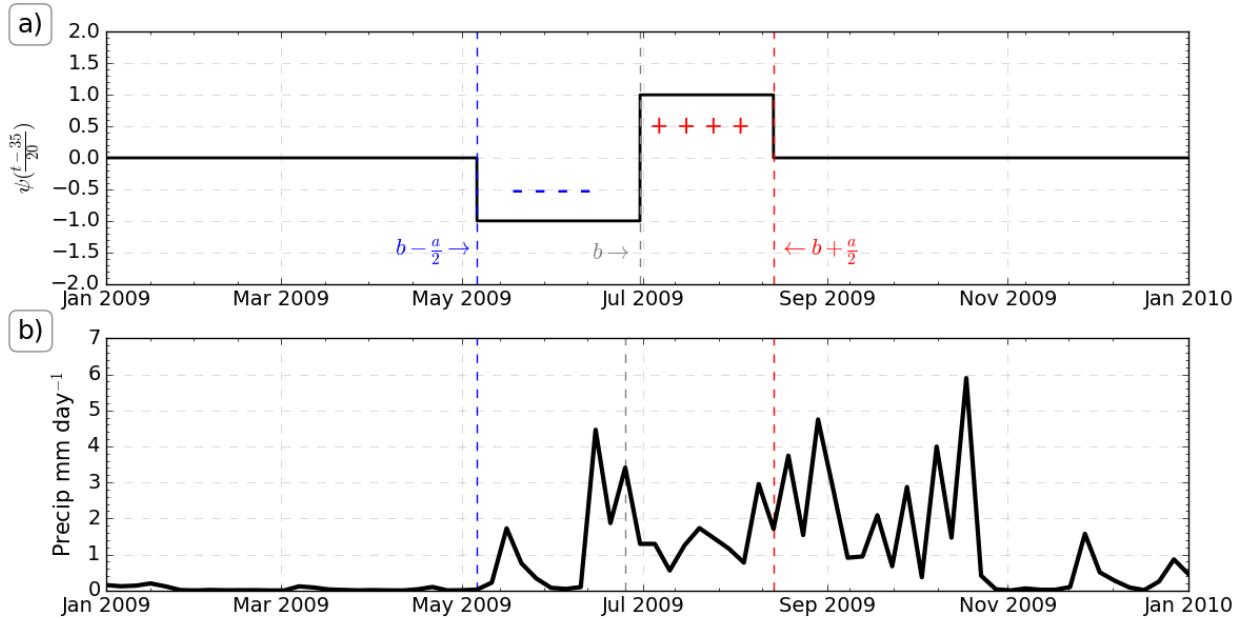

Figure 5.1: (a) Haar wavelet at a dilation $a = 20$ and translation $b = 35$, which is the 35th pentad around June 22. The positive and negative parts of the wavelet are highlighted in red and blue, respectively. (b) CMAP precipitation in 2009 in the North American Monsoon [20-27°N, 110-103°W].

translation or pentad b , highlight a maximum found around June 22 and a minimum found around September 21, which agree well with previous results of mean onset and retreat dates in the North American Monsoon (e.g. Arias et al., 2012; Geil et al., 2013).

5.3.1 Identification of Monsoon Onset and Retreat

Local maxima in the WT highlight positive steps in the precipitation time series with a coherent scale of a pentad steps. This interpretation is then extended to diagnose monsoon onset. The pentad (b^*) corresponding to the maximum of the sum of the transform over a set of scales is defined as monsoon onset (MO), i.e.:

$$MO = b^* \Leftrightarrow \sum_{a_0}^{a_f} W_f(a, b^*) = \max \left(\sum_{a_0}^{a_f} W_f(a, b) \right). \quad (5.3)$$

where a_0 and a_f are the limits of the pentad scales, i.e., the dilation coefficients, b^* is the pentad of maximum $\sum W_f(a, b)$ and the monsoon onset pentad. Similarly, the monsoon retreat pentad is found at the minimum of the sum of the WTs, i.e.,

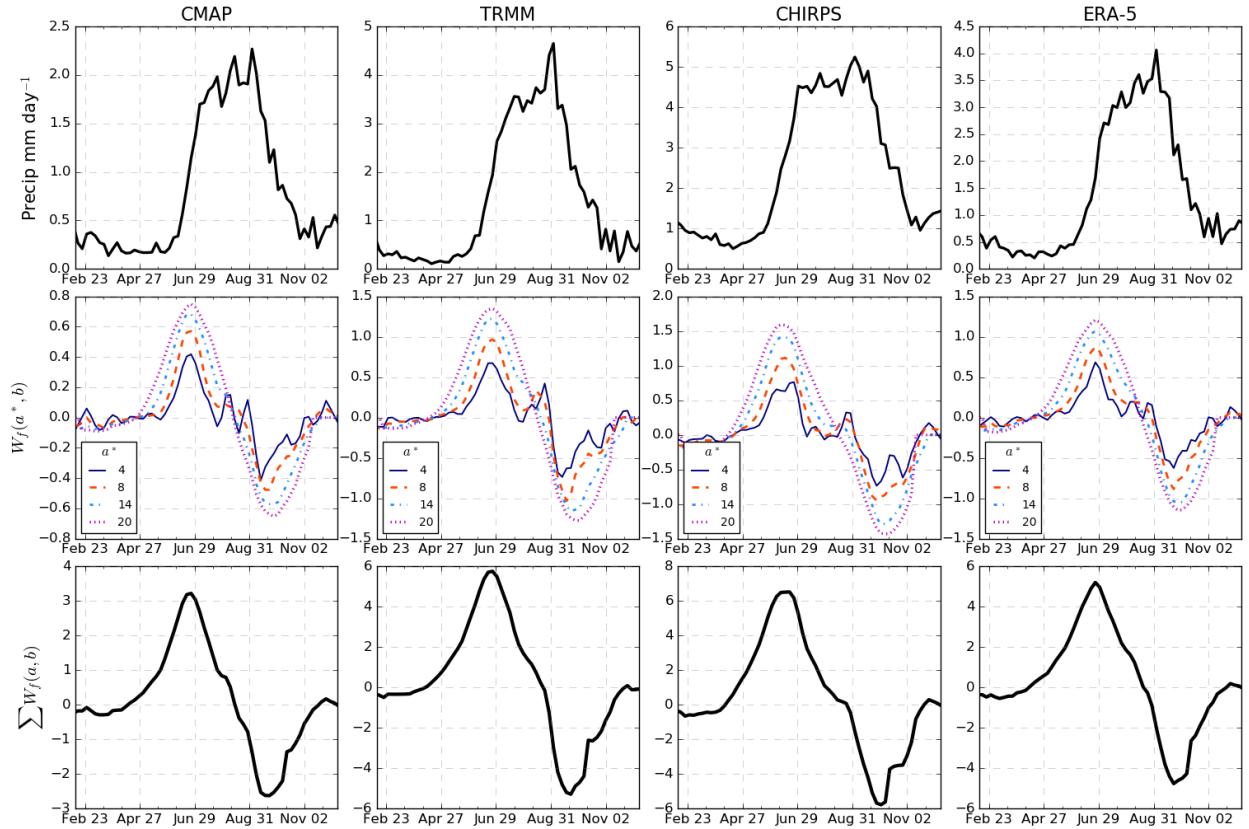

Figure 5.2: (upper) Climatological pentad-mean precipitation in four different observational datasets in the North American Monsoon [19–35°N, 110–103°W]. (middle) The wavelet transform coefficients (mm d^{-1}) for four different dilations a . (lower) The sum of the WT coefficients (mm d^{-1}) over dilations $a = 4, 8, 14, 20$.

$$MR = b^* \Leftrightarrow \sum_{a_0}^{a_f} W_f(a, b^*) = \min \left(\sum_{a_0}^{a_f} W_f(a, b) \right). \quad (5.4)$$

In other words, we seek to find monsoon onset and retreat using the maximum and minimum the wavelet power spectrum over a range of temporal scales. Several sensitivity tests were performed with different dilation coefficients (a) in the different observational datasets, models and regions and a set or vector of dilation scales was found to be optimal. The set of dilation coefficients $\vec{a} = (28, 30, \dots, 54)$ was found to be robust, i.e., was able to capture the onset and retreat dates in all the datasets.

Monsoon onset is defined as the maximum sum of wavelet coefficients, capturing positive gradients within the scales of 14 to 27 pentads (half of the elements of vector a defined above). Monsoon Retreat has a similar definition, capturing the greatest negative gradient

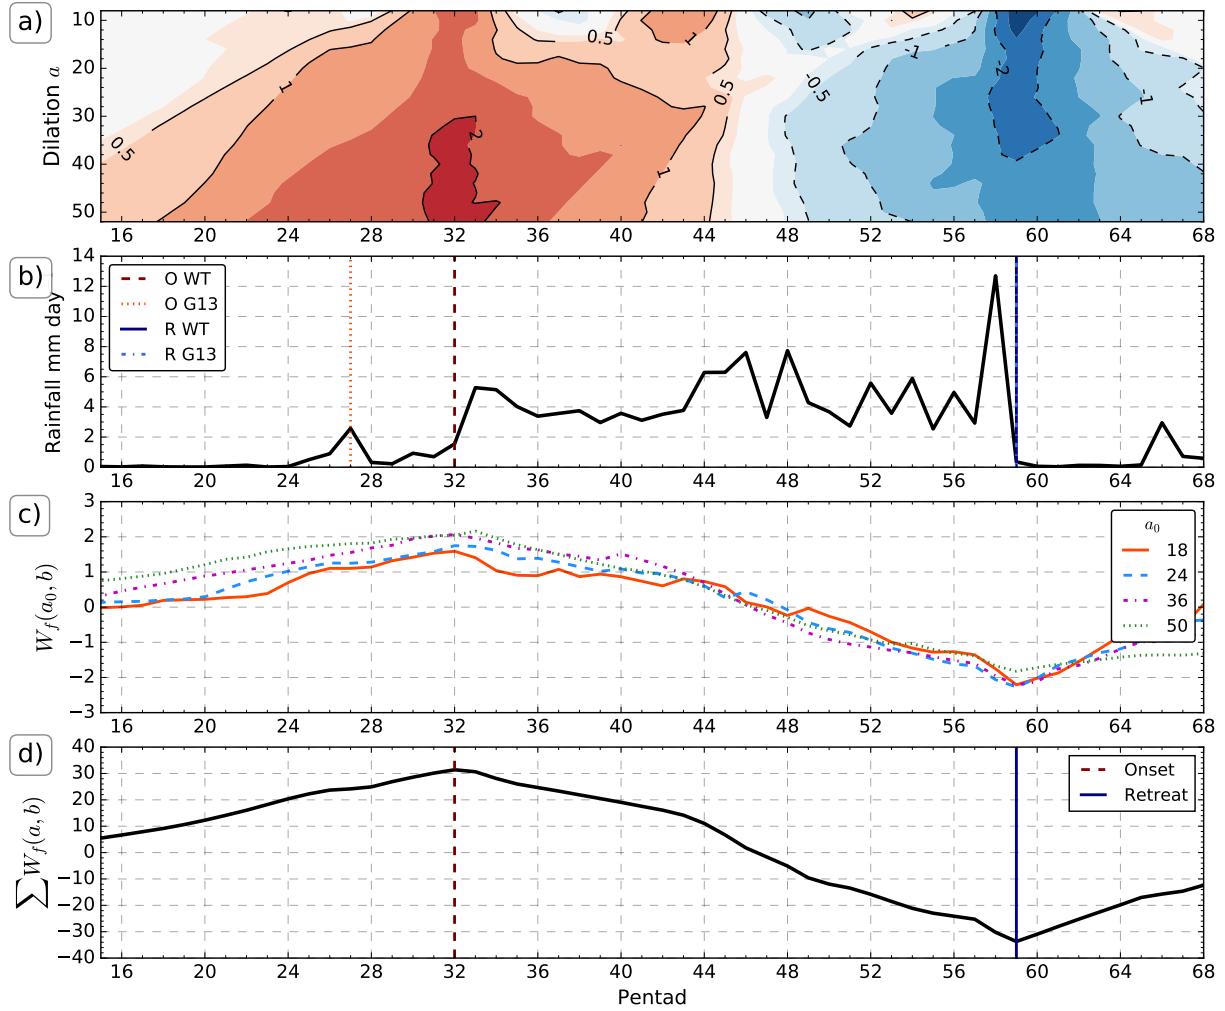

Figure 5.3: Example determination of monsoon onset and retreat dates for the North American Monsoon [20-27°N, 109-103°W] in the TRMM dataset for 2009. (a) WT coefficient matrix (mm d^{-1}) as a function of time and dilation coefficient a . The shading is from -3 to 3 mm d^{-1} with an interval of 0.5 mm d^{-1} . (b) Observed precipitation, the onset and retreat dates as determined by the WT method (dashed) and the threshold method of Geil et al. (2013) (solid) are shown. Note that the date of retreat is diagnosed to be the same between the two methods. (c) The WT coefficients for different dilations. (d) The sum of the WT ($\sum W_f(a, b)$) (mm d^{-1}); the maximum and minimum are shown in red and blue, representing onset and retreat pentads, respectively.

of precipitation over the same pentad scales.

For example, Figure 5.3 illustrates the method in the North American Monsoon in the TRMM dataset for 2009. Figure 5.3a shows the WT coefficient matrix, showing the changes in precipitation for dilations ranging from 10 to 50. A clear signal of positive coefficients is observed between pentads 28 to 34 and a similar negative signal observed in pentads 56 to 60. Figure 5.3b shows the time series of the observed precipitation, which suggests that monsoon

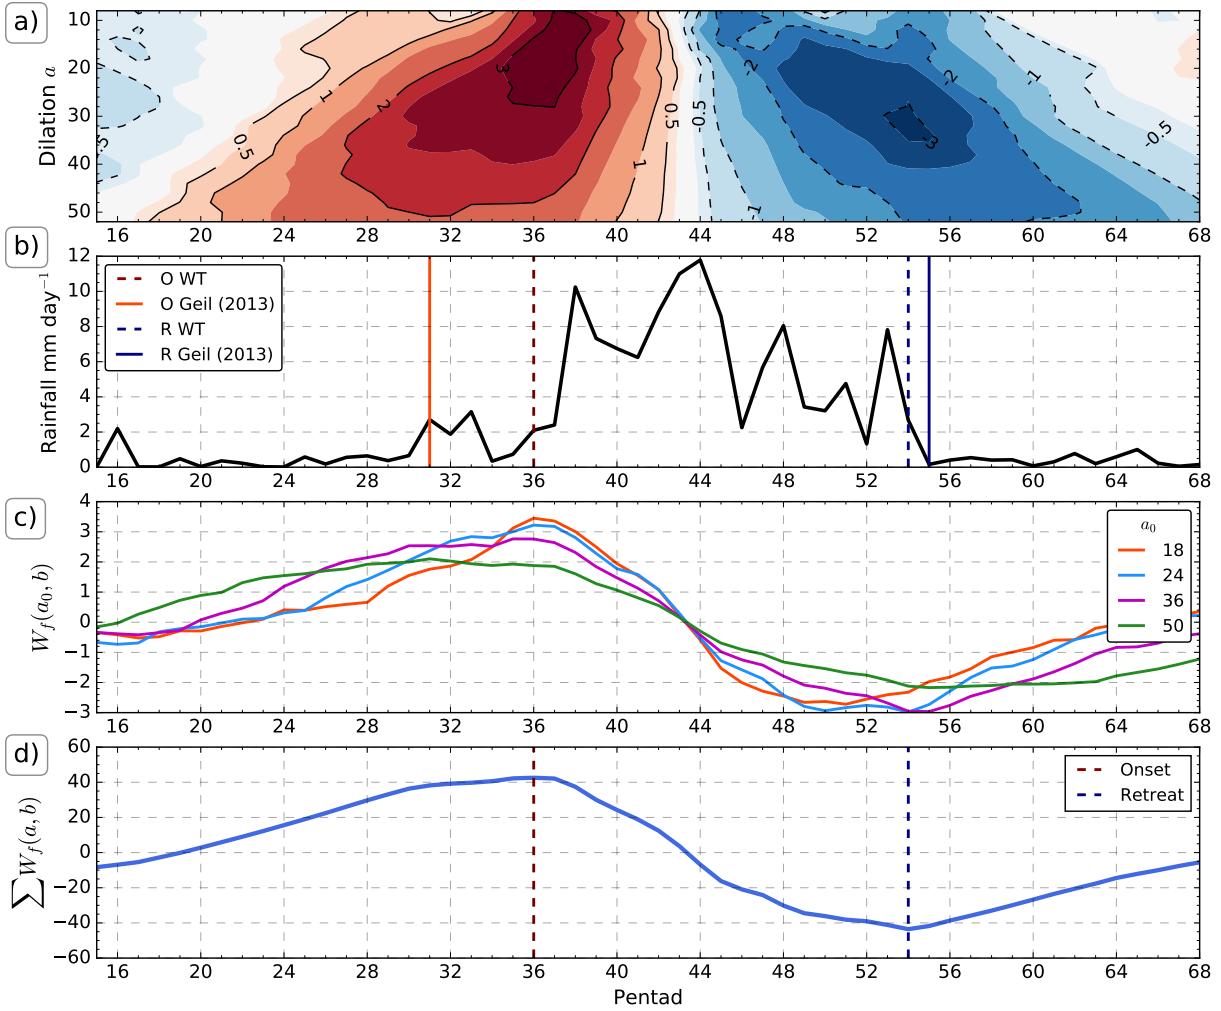

Figure 5.4: As in Figure 5.3, but for a year (1875) in the HadGEMGC3.1 N216 pre-industrial control simulation.

onset occurs sometime between pentads 28 and 34. Observed rainfall rapidly decreases after pentad 59 suggesting that monsoon retreat can be diagnosed around this pentad.

Figure 5.3c shows the WT coefficients as a function of pentad for several dilations (a_0). The coefficients for all scales seem to follow a very similar behaviour, increasing during spring to reach a maximum around pentad 32 and thereafter decreasing to a minimum around pentad 59. When the sum of the wavelet transform coefficients across the dilations is computed (Figure 5.3d) this behaviour becomes much clearer. The maximum and minimum are found at pentads 32 and 59, respectively and these pentads define the onset and retreat times. For comparison, the results from the method of Geil et al. (2013) are shown in Figure

5.3b, indicating that this method may have found an earlier onset.

As a proof of concept, Figure 5.4 shows a similar example using precipitation area-averaged in the same region but using model data from the piControl simulation of HadGEM3 GC3.1 N216. The results show that the WT method can capture the onset and retreat dates with relatively high skill and that these dates are different from the dates computed using the method of G13, with the threshold method suggesting an earlier onset and a later retreat.

5.3.2 Extension for Application to the MSD signal

The wavelet method can be extended to characterise the shorter scale variations of precipitation of the MSD in Central America and the Caribbean. First, the monsoon onset and retreat dates are determined in the time series from the area-averaged precipitation in the MSD region via the approach described in the previous section. Once the onset and retreat dates are established, an additional wavelet analysis determines the dates in which the MSD starts and ends. The onset and end of the drier period of the MSD can be found by computing the wavelet transform again but using smaller dilations and over a limited temporal range. In particular, the WT is only calculated in the 20 pentads before and after the dates defining monsoon retreat and onset, respectively. The MSD Onset (MSDO) and MSD End (MSDE) are defined as the minimum and maximum, respectively, of the sum of the wavelet transforms (equations 5.3 and 5.4) using dilation coefficients $\vec{a}^* = (10, 12, \dots, 24)$. The diagnosis of the onset and end of the MSD is also robust to using other dilation coefficients of similar magnitude.

Figure 5.5d illustrates the use of the WT method to determine the dates of MSDO and MSDE for the precipitation of 2017 in ERA-5. Figure 5.5a depicts the wavelet covariant transform matrix, showing the W_f coefficients for each dilation a at each pentad b . The onset of rainfall is diagnosed around the time-steps of highest positive W_f coefficients – around pentads 24 to 32 for almost all dilations. These positive coefficients are followed by a period of negative values from pentad 32 to pentad 40, which represent the decrease in precipitation, or relative drought, in the midsummer. The MSD is followed by another period of positive coefficients from pentad 44 to pentad 52, illustrating the so-called second peak of precipitation and, finally, a period of negative coefficients associated with monsoon retreat.

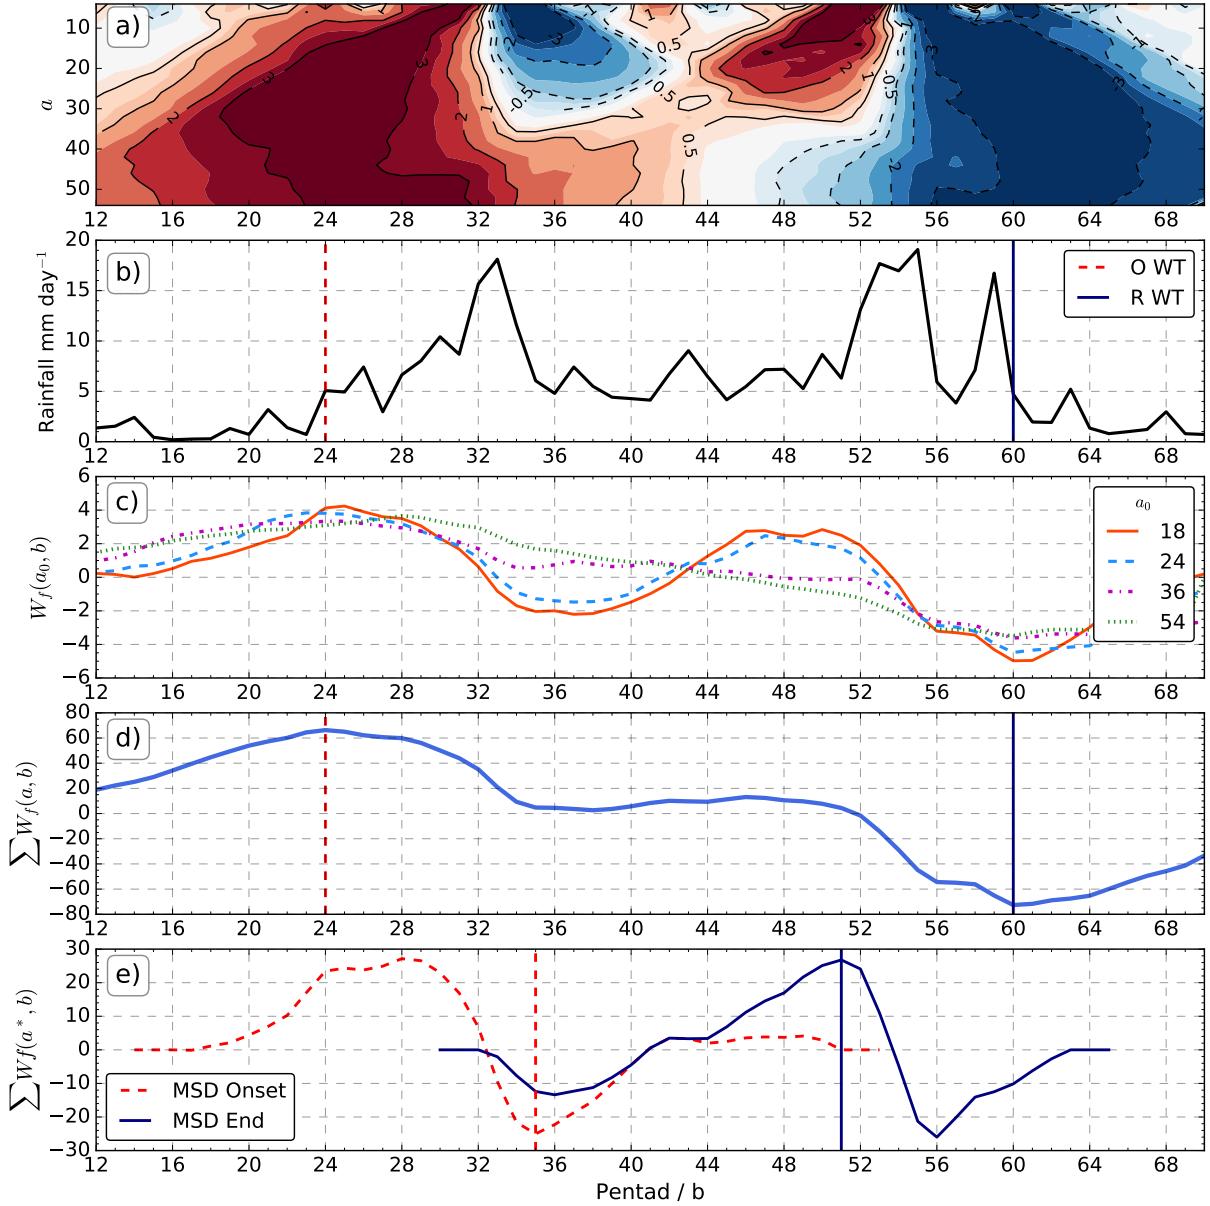

Figure 5.5: Example characterisation of the MSD [11-19°N, 95-85°W] using ERA-5 data for 2017. (a) Wavelet transform spectra, (b) observed precipitation with the onset and retreat pentads shown in red and blue, respectively. (c) Wavelet transform coefficients for four different dilations (mm d^{-1}). (d) The sum of the wavelet transform coefficients (mm d^{-1}) for $a = 28, \dots, 51$. (e) The sum of $W_f(a, b)$ (mm d^{-1}) for dilation coefficients $a = 12, \dots, 24$ showing the start (MSD Onset) and end (MSD End) of the midsummer drought.

The coefficients of the wavelet transform ($W_f(a_0, b)$) for selected dilations a_0 (Figure 5.5c) show that the smaller dilations are more sensitive to smaller scale variations in the time series and longer dilations better highlight the long-term change of the time series. For example

$a_0 = 18$ shows signs of a MSD by showing two local maxima and two local minima, whereas $a_0 = 54$ only shows a local maximum and a local minimum associated with onset and retreat.

The maximum and minimum of the sum over all dilations (Figure 5.5) depict the rainfall onset and retreat dates, respectively. The second wavelet transform $W_f(a^*, b)$ is computed over smaller dilation coefficients (a^*) near the onset and retreat dates as described above to highlight the MSDO and the MSDE. Figure 5.5e shows the sum of the wavelet transform coefficients $W_f(a^*, b)$ and the pentad of the MSDO, 34, and MSDE, 49, corresponding to the minimum and maximum of the sum of these wavelet transform coefficients, respectively.

The strength of the MSD can be measured through the maximum and minimum sum of the coefficients $\sum W_f(a^*, b)$ used to define the start and end dates of the MSD. For example, in Figure 5.5e the minimum of the $\sum W_f(a^*, b)$ was -20 mm d^{-1} found at pentad 35 and an opposite local maximum of $+20 \text{ mm d}^{-1}$ at pentad 49. These two values, hereafter *coef1* and *coef2*, provide a quantitative measure of the strength of the MSD for this year in this dataset and will be used to measure the spatial and temporal variability of the magnitude of the MSD in the different datasets.

5.3.3 Comparative Methodologies

For validation purposes, the wavelet transform method is compared with existing methods which determine onset and retreat in the North American and Indian monsoons. The threshold methods of Geil et al. (2013) (hereafter G13) and Arias et al. (2012) (hereafter A12) are compared to the results of the wavelet transform in the North American Monsoon. G13 used a threshold of 1.3 mm day^{-1} for at least 3 days for onset and 7 days for retreat for daily TRMM observations. This study, in contrast, analyses most of the data on the pentad-scale, so we adapt this method for TRMM to the same threshold value, but the onset pentad is the first pentad above the threshold whereas for retreat, we require rainfall to be below the threshold for two consecutive pentads. The method of A12 defines onset with two conditions. The first condition to find the onset pentad is that six out of the eight subsequent pentads must have rain-rates above the annual-mean climatological rainfall. The second condition is that at least six out of the eight previous pentads must be below the annual-mean climatological rainfall. The opposite definition is used to determine the pentad of monsoon retreat.

In relation for the Indian Monsoon region, a commonly used metric is the hydrological onset and withdrawal index (HOWI) which is based on moisture transport over the Arabian Sea (Fasullo and Webster, 2003; Sahana et al., 2015; Chevuturi et al., 2019). To compute the HOWI index, first, the vertically integrated moisture transport (χ) is computed from daily ERA-5 data in the Arabian sea, as described by Fasullo and Webster (2003), i.e.:

$$\chi = \frac{1}{g} \int_{p_0}^0 q \mathbf{V} dp, \quad (5.5)$$

where g is the gravitational acceleration, p are the pressure levels, q is the specific humidity and \mathbf{V} is the wind vector. The VIMT is then normalized using the transformation:

$$HOWI = 2 \left(\frac{\chi - \min(\bar{\chi})}{\max(\bar{\chi}) - \min(\bar{\chi})} \right) \quad (5.6)$$

where χ is the unnormalized time series, $\bar{\chi}$ is the mean seasonal cycle of the unnormalized index and HOWI is the normalized index. The onset date is defined as the first day of each year where the HOWI index is greater than zero and the retreat date is the first day after the onset date that the HOWI index is negative (Fasullo and Webster, 2003; Sahana et al., 2015). The necessary daily data of moisture and wind speed on sufficient vertical levels to compute the HOWI index in the MOHC submissions to CMIP6 was not available, so the HOWI index can only be computed using ERA5 and will be compared to the WT method used on the observational gridded datasets.

5.4 Results

The monsoon onset and retreat dates were determined for each year in each observational and model dataset for the Indian, North American and MSD regions using the methods described in the previous section. The calculations were performed for area-averaged precipitation time series representative of the core regions defining these monsoons. [Several sensitivity tests show there is little sensitivity to the performance of the WT to the size of the box, relative to other methods, however, the mean values of retreat and onset dates are very sensitive to the regions chosen for the averaging.](#) Calculations were also made at grid-box scales to illustrate the spatial distribution of the onset and retreat dates.

5.4.1 The North American Monsoon

Table 5.1 shows the mean onset and retreat dates estimated using the G13, A12 and WT methods for precipitation time series averaged over the North American monsoon. The table reports the results for three observational datasets, ERA-5 reanalysis and five climate model experiments. The observations agree that the onset date is found at pentad 33 (around June 15), according to the WT and the method by G13. However, the method of G13 reports a mean retreat date that is one pentad later than the WT method, i.e., around October 7th for G13 method and October 2nd for the WT. The method by A12 disagrees with G13 and the WT methods for both onset and retreat mean pentads, in both cases finding an earlier onset (pentad 30) and retreat (pentad 54) for all the observational datasets.

The climate models reasonably represent the mean onset and retreat dates, as only the

Table 5.1: Mean (standard deviation) pentads of monsoon onset (O) and retreat (R) in the North American Monsoon [110°-103°W, 20°-27°N] for observational datasets, reanalysis and model output with the wavelet transform method WT, G13's and A14's method. Pentad 34 corresponds to the period between June 17-22 and pentad 54 to the period Sep 27 - Oct 1. The results from the WT method in the model experiments which are statistically different to both the CMAP and CHIRPS results at the 95% confidence level, according to a Welch's t-test, are shown in bold.

Dataset / Experiment	WT O	WT R	G13 O	G13 R	A12 O	A12 R
TRMM	33.3 [±1.8]	55.8 [±1.9]	33.0 [±1.7]	56.6 [±1.4]	30.4 [±1.7]	53.8 [±2.0]
CMAP	33.2 [±1.6]	55.0 [±2.1]	36.0 [±3.3]	55.7 [±1.8]	31.7 [±3.0]	54.5 [±3.3]
CHIRPS	32.5 [±1.5]	54.7 [±1.9]	33.6 [±1.7]	56.1 [±1.4]	30.1 [±1.7]	53.6 [±2.5]
ERA-5	33.5 [±1.8]	55.5 [±2.0]	33.6 [±1.8]	56.4 [±1.4]	30.9 [±1.7]	53.3 [±2.3]
GC3 N216-pi	33.7 [±2.0]	55.1 [±1.8]	32.6 [±2.5]	55.9 [±2.3]	32.4 [±2.5]	53.8 [±3.8]
GC3 N96-pi	33.7 [±2.2]	55.0 [±2.1]	32.7 [±2.9]	56.3 [±2.0]	31.9 [±2.6]	54.1 [±4.1]
GC3-hist	33.8 [±2.3]	55.1 [±2.1]	33.3 [±2.9]	56.0 [±2.2]	31.9 [±2.6]	53.7 [±4.0]
UKESM-pi	34.5 [±2.1]	54.8 [±2.1]	34.1 [±2.9]	56.1 [±1.9]	33 [±2.6]	53.9 [±4]
UKESM-hist	34.3 [±2.2]	54.3 [±2.2]	34.4 [±3.2]	55.6 [±2.1]	33.1 [±3.0]	53.2 [±4.2]

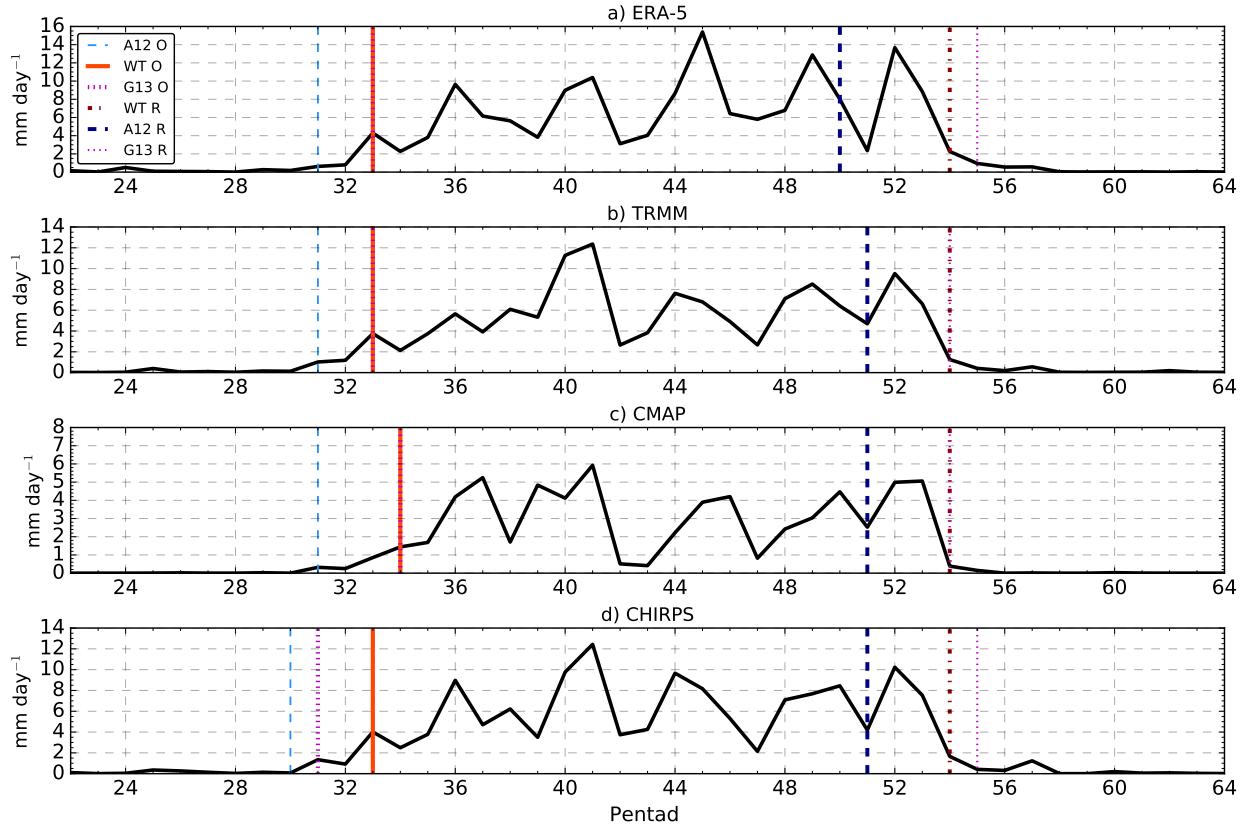

Figure 5.6: Pentad-mean precipitation for the North American Monsoon in 2010 in four precipitation datasets showing the onset and retreat pentads as diagnosed by the WT, the A12 and G13 methods. The area used to average the precipitation is illustrated in in Figure 5.7b).

onset dates from both experiments of UKESM1 are statistically different to the results of CMAP and CHIRPS. The similarities in onset and retreat dates confirm that the seasonal cycle in the North American monsoon is very well represented by these models, as suggested by chapter 4. In the results of the simulations, A12 also produces an earlier onset and retreat dates when compared to the other two methods of about 1.5 pentads, but this difference is within the uncertainty range given by the interannual variability of the model data which is largest for A12.

Figure 5.6 compares the estimated onset and retreat dates using the three methods for the 2010 North American Monsoon using the three observational datasets and ERA5. A12 shows an earlier onset and retreat in all the datasets compared with the WT and G13 which agree in almost every dataset. The WT method estimates the retreat and onset dates more consistently across datasets relative to the other methods.

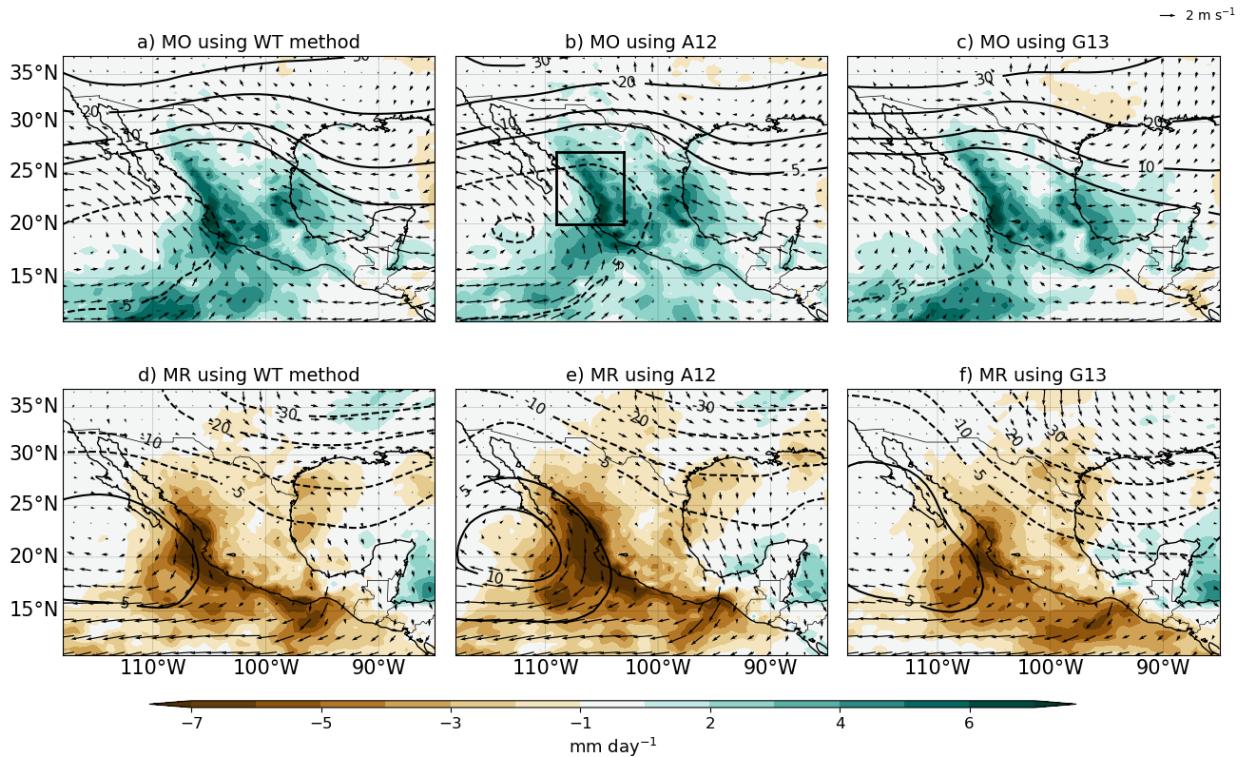

Figure 5.7: Precipitation (color contours), low level wind at 850-hPa and geopotential height (line contours) at 500 hPa anomalies for (a, b, c) the difference between the 10 days after monsoon onset and 10 days prior to onset (MO) using onset dates from (a) the WT (b) Arias et al. (2012) and (c) Geil et al. (2013). (d, e, f) are as in (a, b, c) but for monsoon retreat. The data and dates are obtained from ERA-5, and the area for the average is shown in the box in b).

The meteorological changes associated with onset and retreat of the North American Monsoon (Figure 5.7) are illustrated as the composite differences of the precipitation, wind and geopotential changes 10 days prior to and after onset and retreat. These changes to the circulation and precipitation are reasonably similar for all the three methods. The impact of monsoon onset in precipitation is diagnosed to be slightly stronger by A12 compared to WT or G13. The WT method shows a very similar pattern and magnitude of the circulation and precipitation anomalies of onset and retreat when compared to the other two methods. The method by G13 produces the weakest anomalies, particularly of precipitation whereas the method by A12 produces the strongest precipitation and geopotential anomalies, particularly at retreat.

Figure 5.8 shows the spatial distribution of the mean onset and retreat dates in the North American Monsoon region for various datasets. There is high agreement between

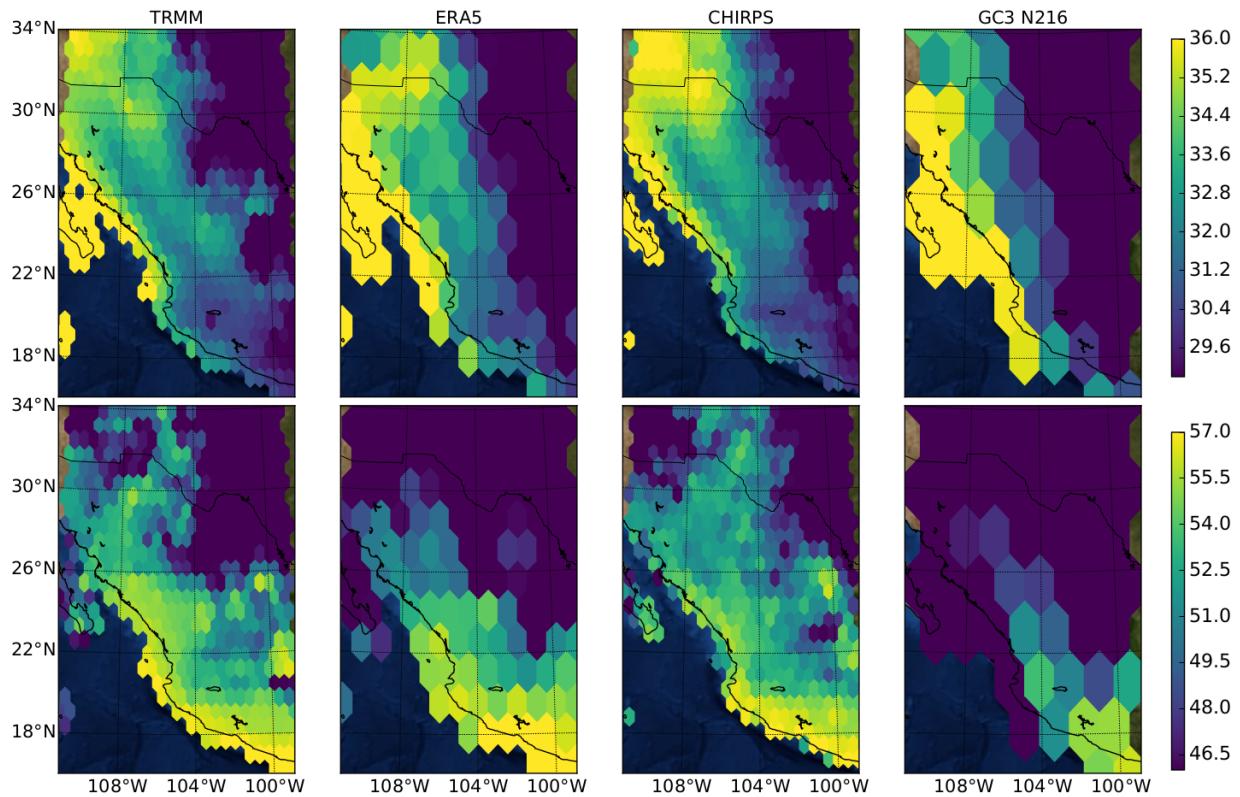

Figure 5.8: Rainfall onset (upper) and retreat (lower) mean pentads in the North American Monsoon for observations and a climate model output using the WT method.

TRMM, CHIRPS and ERA5 on the spatial pattern of mean onset and retreat dates. Onset in western Mexico is around pentad 31 (around June 1st), whereas in Chihuahua and Sonora the rainy season begins shortly after pentad 35 (June 22). The pattern in the medium-resolution simulation GC3 N216 piControl is consistent with observations, particularly during onset. However, the spatial pattern of the mean retreat dates in the northern regions of the monsoon show an earlier than observed retreat, possibly associated with the dry bias in this region in these models (see chapter 4).

5.4.2 The Indian Monsoon

Table 5.2 compares the mean onset and retreat dates of the Indian Monsoon as computed from the HOWI index using ERA5 data, and the WT used for gridded precipitation datasets. The onset and retreat dates from the HOWI index were converted from the daily to the pentad-scale to compare with the WT. The mean onset date for the HOWI index is May 27th

Table 5.2: Mean (standard deviation) pentads of monsoon onset (MO) and retreat (MR) in the Indian Monsoon using the WT method on observed, reanalysed and modelled time series as well as for the HOWI index. The region over which precipitation was area-averaged for the WT method was [75°-83°E, 18°-24°N]. The mean onset and retreat dates that are significantly different to the 99% confidence level to the CMAP dataset are shown in bold.

Dataset	MO	MR
TRMM	31.6 [± 1.8]	53.2 [± 1.9]
CMAP	31.8 [± 1.6]	53.3 [± 2.6]
CHIRPS	31.5 [± 1.4]	53.4 [± 1.9]
ERA-5	31.8 [± 1.9]	52.7 [± 2.6]
GC3 N216-pi	34.4 [± 1.3]	50.5 [± 1.9]
UKESM-pi	36.1 [± 3.1]	51.9 [± 3.2]
UKESM-hist	36.0 [± 3.9]	51.8 [± 3.3]
GC3 N96-pi	35.5 [± 1.8]	51.8 [± 2.3]
GC3-hist	35.7 [± 2.1]	51.5 [± 2.8]
HOWI (ERA5)	29.5 [± 2.3]	49.3 [± 2.4]

between pentads 29 and 30, and retreat is between pentads 49 and 50, around September 3rd. The mean onset date found using the WT method for the four observational datasets was pentad 32, about two pentads later than the HOWI index. The mean retreat date for the WT method (pentad 53) was two pentads later than the HOWI results.

Overall, the models exhibited later than observed onset (+4 pentads) and earlier retreat (-2 pentads) dates. The differences between the hydrological determination of onset and retreat dates, through HOWI, and the WT method on gridded precipitation datasets is statistically significant, according to a Welch's t-test comparing the HOWI and all the gridded datasets. These differences may be due to the different regions where each method is defined, i.e., HOWI is defined over the whole of the Arabian Sea where an earlier onset would be expected when compared to rainfall over mainland India, where the WT method was applied.

Figure 5.9 shows the differences between the WT (based on ERA5 precipitation) and HOWI methods in their characterisation of the meteorological changes associated with onset and retreat. The comparison of precipitation and moisture fluxes at 850 hPa anomalies 10 days prior to and following monsoon onset and retreat show that the HOWI index better captures the moisture transport in the Arabian Sea whereas the WT method best captures precipitation differences over mainland India. The HOWI index characterisation of the

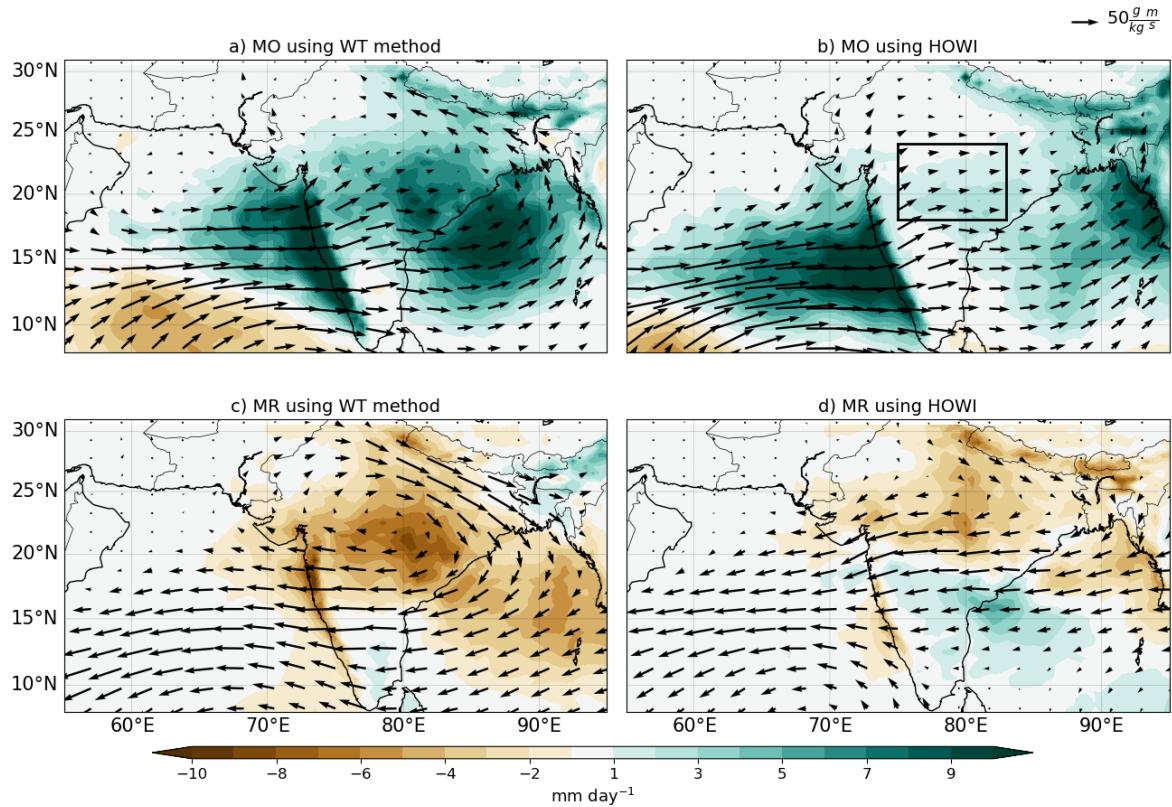

Figure 5.9: Precipitation anomalies (color contours) and the moisture flux vectors calculated from the product of specific humidity (q) and wind (\vec{u}) at 850 hPa. (a, b) shows the difference between the 10 days after monsoon onset and 10 days prior to MO using (a) the WT and (b) the dates estimated using the HOWI index. (c, d) are as defined in (a, b) but for MR. The dates are calculated from ERA5 data averaged over the box in panel b).

moisture flux in the Arabian Sea may be out-of-phase with precipitation over mainland India, and this lag could possibly explain some of the results of Table 5.2.

The WT method is also able to capture onset and retreat dates and the associated anomalies within the climate model output. Figure 5.10 shows the precipitation and moisture transport anomalies around the onset and retreat of the Indian monsoon in three different climate model experiments. While the models show significant biases in the timings of the monsoon, according to a Welch's t-test (Table 5.2), the patterns of rainfall and moisture transport anomalies to the observations around both onset and retreat agree well with reanalysis. It is interesting to note that the medium-resolution configuration simulates a stronger decrease of precipitation at the end of summer monsoon period, also observed as a stronger moisture flux anomaly, relative to the two lower resolution simulations.

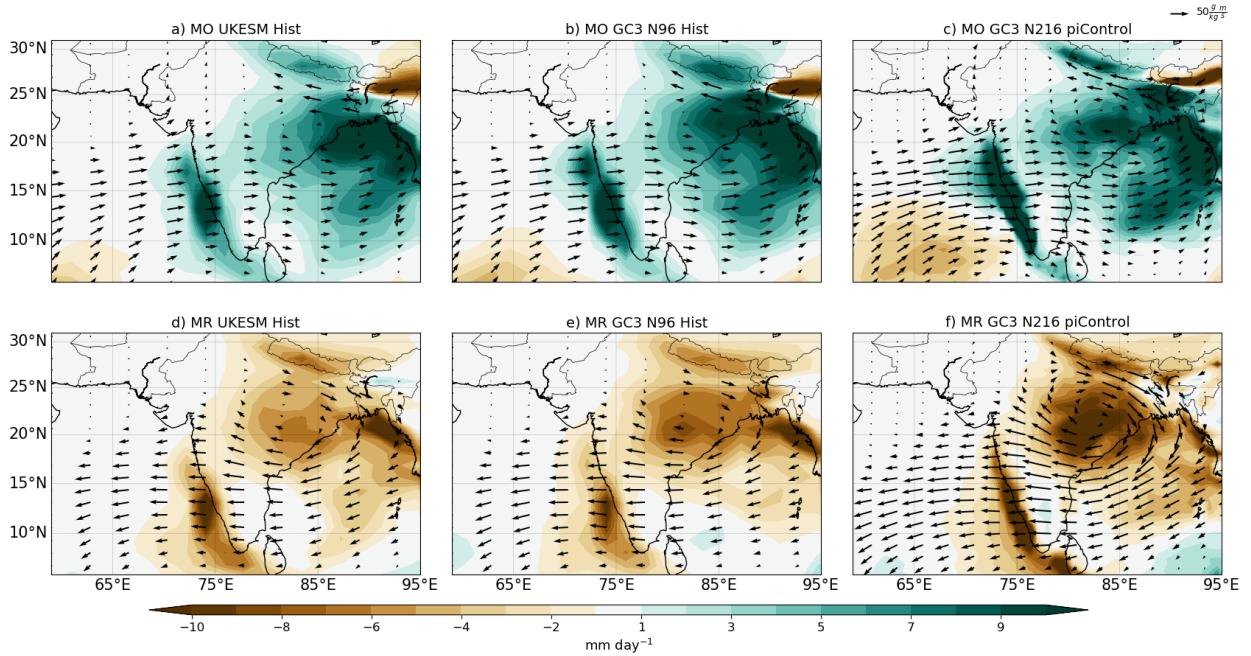

Figure 5.10: As in Figure 5.9 but showing onset and retreat for three different climate model experiments: (a, d) UKESM1 historical, (b, e) HadGEM3 GC3.1 N96 historical, (c, f) HadGEM3 GC3.1 N216 piControl.

The spatial distribution of the mean onset and retreat dates of the Indian monsoon as characterized by the WT method (Figure 5.11) shows that the mean onset and retreat dates vary greatly spatially on the southern tip of the subcontinent. While most of northern India has a mean onset date around pentad 33, the western coast shows an earlier onset by about one or two pentads. There is high agreement in the onset date between the three observational datasets and the reanalysis over mainland India and between TRMM and ERA5 over the western coast of India. The earliest onset is found on the western coast around pentad 25-27 and extending to central India by pentad 31. The GC3 N216 simulation, however, shows a later onset than observed by about two pentads in most regions. In contrast, the spatial pattern for the mean retreat date shows higher spatial variability between the western and eastern coasts of India. CHIRPS shows the latest retreat dates over the south-central states when compared to TRMM and ERA-5.

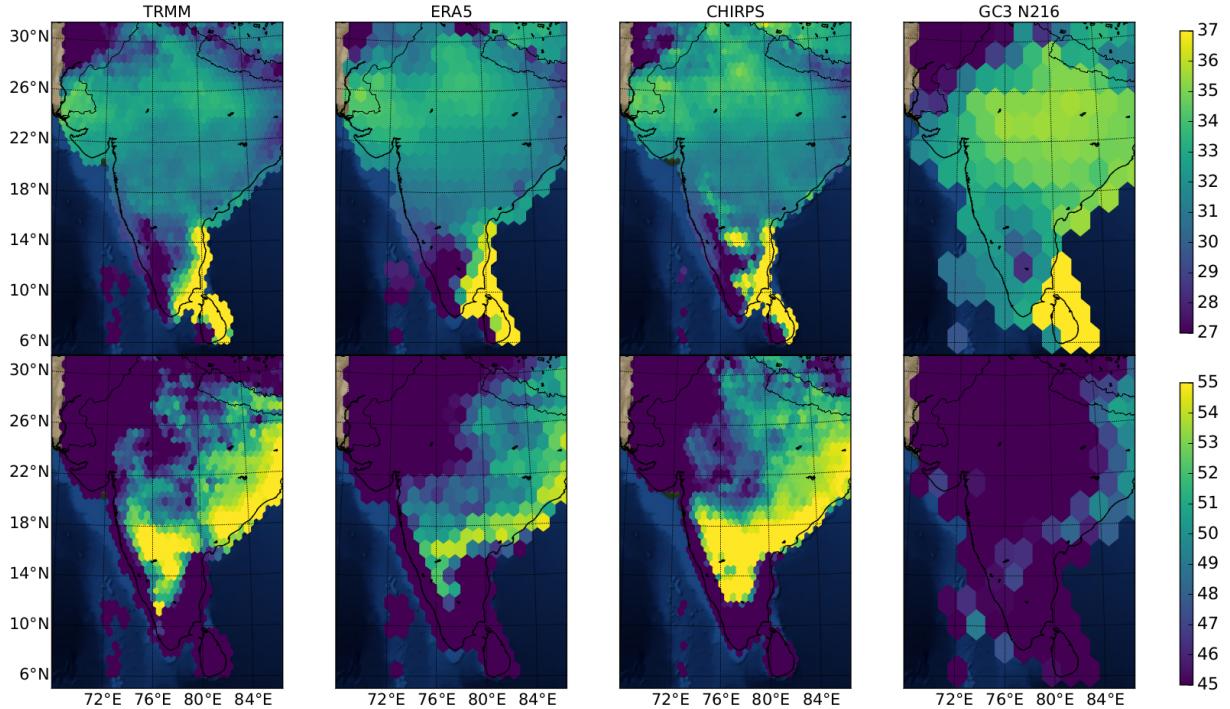

Figure 5.11: As in Figure 5.7 but for the Indian Monsoon.

5.4.3 The midsummer drought

Results from the application of the wavelet transform to the MSD, including the mean onset and retreat dates as well as the start and end dates of the MSD period, are reported in Table 5.3. The mean onset date in the observations is around pentad 27 (May 14), whereas the retreat date is around pentad 61 (October 31). The end of the so-called first-peak period, or start of the relatively drier period (MSD), referred to in this thesis as MSD onset (MSDO) is consistently found in all the observed datasets to be around pentad 36 (around June 29). The end of the drier period or start of the second peak, referred to in this thesis as MSD end (MSDE) is also consistently determined to be between pentads 48 to 49 in the four observational datasets. In other words, the MSD has a mean duration of 12 pentads, or around two months, from late June to late August. In the MOHC simulations, the MSD starts slightly later than observed by about two pentads, and ends about one pentad later than observed around September 10.

Figure 5.12 shows the rainfall anomalies associated with the different periods (stages) of the rainy season in southern Mexico and Central America. These include monsoon onset and

Table 5.3: Mean pentads of monsoon onset (MO), rainfall retreat (MR), MSD Onset (MSDO) and MSD End (MSDE) in the MSD region [11-19°N, 95-85°W, illustrated in Figure 5.12a.] estimated through the WT method. Pentad 35 corresponds to the period between June 22-27 and pentad 52 to the period Sep 13-18. The model dates shown in bold are statistically different from CMAP and CHIRPS results to the 99% confidence level according to a Welch's t-test.

Dataset	MO	MR	MSDO	MSDE	coef1	coef2
TRMM	25.8 [±2.2]	61.6 [±3.1]	35.9 [±2.4]	49.0 [±4.1]	-9.5 [±4.2]	10.4 [±5.4]
CMAP	26.7 [±1.9]	60.6 [±3.3]	36.5 [±2.6]	48.0 [±4.2]	-7.1 [±4.2]	7.7 [±4.3]
CHIRPS	26.7 [±2.3]	61.4 [±3.1]	36.5 [±2.7]	48.3 [±3.5]	-4.7 [±2.7]	5.5 [±3.2]
ERA-5	26.5 [±2.2]	61.8 [±3.2]	36.1 [±2.7]	48.8 [±3.5]	-10.7 [±5.4]	11.8 [±6.6]
UKESM-pi	27.4 [±2.4]	61.9 [±3.2]	38.2 [±2.7]	49.1 [±2.7]	-18.2 [±8.7]	14.6 [±8.0]
GC3 N96-pi	26.9 [±2.6]	62.3 [±3.5]	37.8 [±2.1]	49.9 [±3.1]	-21.7 [±9.4]	16.8 [±8.0]
GC3 N216-pi	26.9 [±2.3]	62.2 [±3.5]	38.4 [±2.1]	50.0 [±2.7]	-23.5 [±8.0]	14.1 [±6.7]
GC3-hist	26.9 [±2.7]	62.8 [±3.7]	37.8 [±2.4]	50.3 [±2.6]	-19 [±8.7]	17.1 [±8.4]
UKESM-hist	28.5 [±2.7]	62.8 [±3.5]	38.7 [±2.8]	50.1 [±2.7]	-20.3 [±10.1]	14.9 [±8.3]

retreat, and the start and end of the MSD, the MSDO and MSDE, respectively. For each stage, we compared the anomalies computed by separating the stages using the WT method or the dates of the climatological monsoon onset, retreat, MSDO and MSDE as found in Table 5.3. In this way, the ability of the WT method to characterise rainfall variations is tested against a first best guess – the climatological mean dates.

Overall, using the dates for MSDO and MSDE from the climatological dates results in weaker anomalies than compositing via the specific dates for each year obtained with the WT method. Even though the area-averaged signal used to diagnose the different MSD stages focuses on a small region of southern Mexico and northern Central America, the anomalies associated with the onset and end of the MSD (Figures 5.12f, h) extend across the East Pacific warm pool, most of the western coast of Mexico and into to the Caribbean Sea and Cuba. This result suggests that the MSD is not the result of micro-scale processes

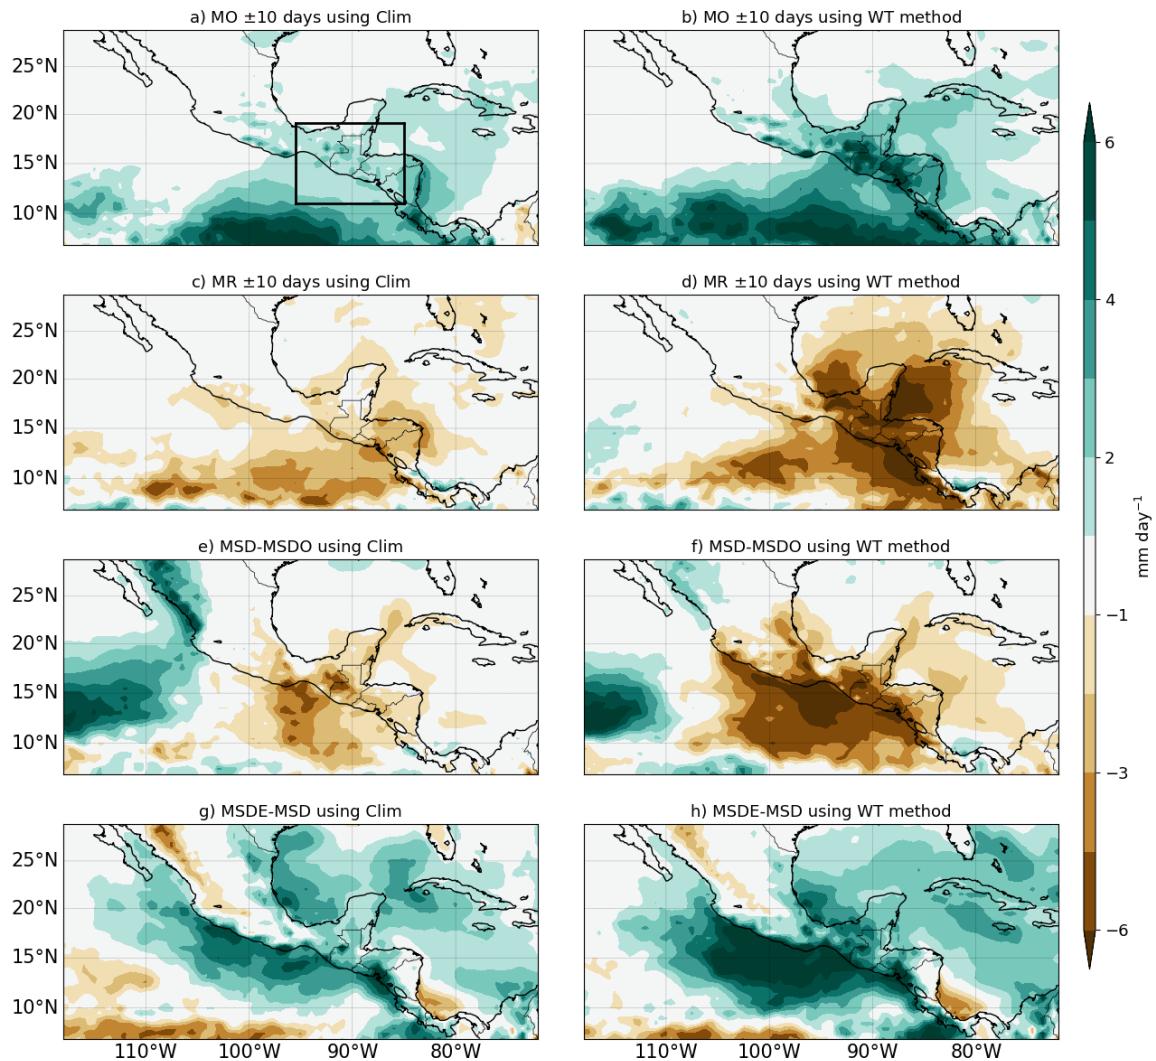

Figure 5.12: Precipitation anomalies for (a, b) the difference between the 10 days after monsoon onset and 10 days prior to onset (MO) using (a) the climatological dates of onset and (b) the dates estimated using the WT method. The black rectangle in a) shows the MSD area used to average the precipitation throughout this study.

but the relatively large extent of the MSD precipitation pattern indicates this is a regional feature associated with regional-scale processes. This result suggests that the MSD is part of a regional-scale process on the result of local-scale processes.

The analysis of individual years of observed precipitation in the selected area-averaged time series showed that not all years showed a bimodal signal in the area-averaged pre-

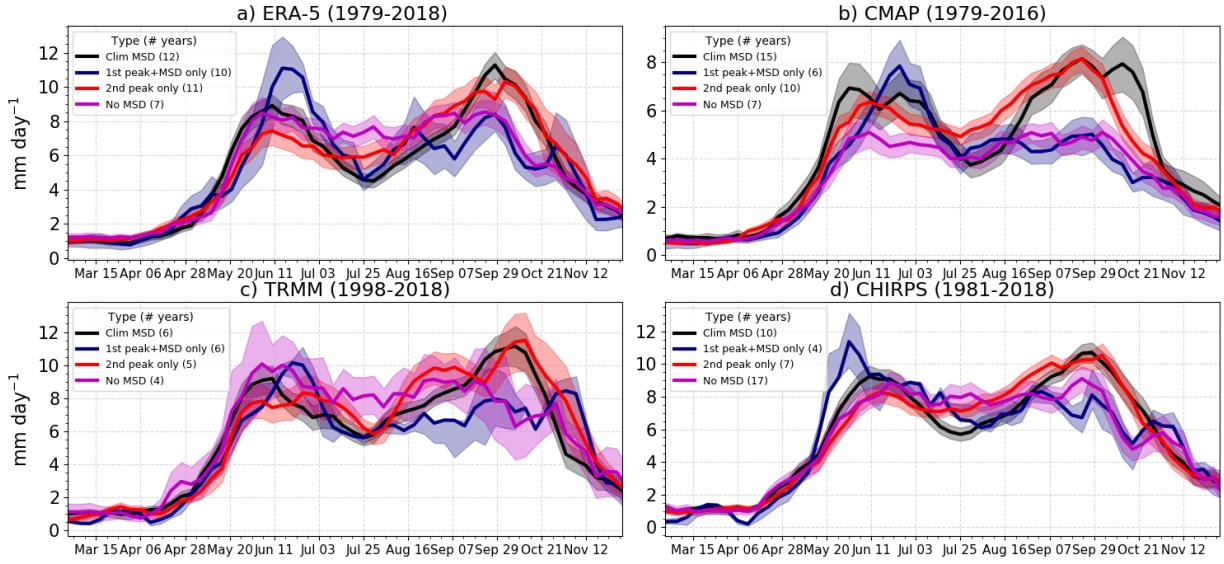

Figure 5.13: Pentad-mean precipitation in years differentiated by MSD characteristics in four datasets: (a) ERA-5, (b) CMAP, (c) TRMM and (d) CHIRPS. The shading for each line represents first to third quantile of the distribution provided a bootstrapping with replacement all the years in each composite 10000 times.

cipitation (Fig. 5.13). In fact, a given year could be classified as having (1) a canonical two-peak structure separated by an MSD, (2) only having a first peak and an MSD but no second peak, (3) only having a second peak but no clear MSD or (4) a plateau-like monsoon season with no MSD-type variations (see Fig. 5.13).

Due to this year-to-year variability in the characteristics of the seasonal cycle, an objective measure was defined to determine whether a signal presented a robust MSD-bimodal seasonal cycle. For this purpose, the WT algorithm was applied to randomly generated precipitation time series. The random time series are constructed by randomly sampling observations in the wet and dry seasons. The pentad-mean onset and retreat dates from Table 5.3 were used to composite the observations into dry and wet distributions.

For a random time series that aims to mimic one year of precipitation, the rainfall values for each pentad in the year are randomly selected from the dry or wet distributions, depending on the pentad. In this way, the value of a given pentad of the random time series may have been observed at a different pentad; the only constraint is that the random values come from pentads that were observed in the same season: dry or wet. The logic behind this approach is that in most monsoon regions, the peak monsoon rainfall should

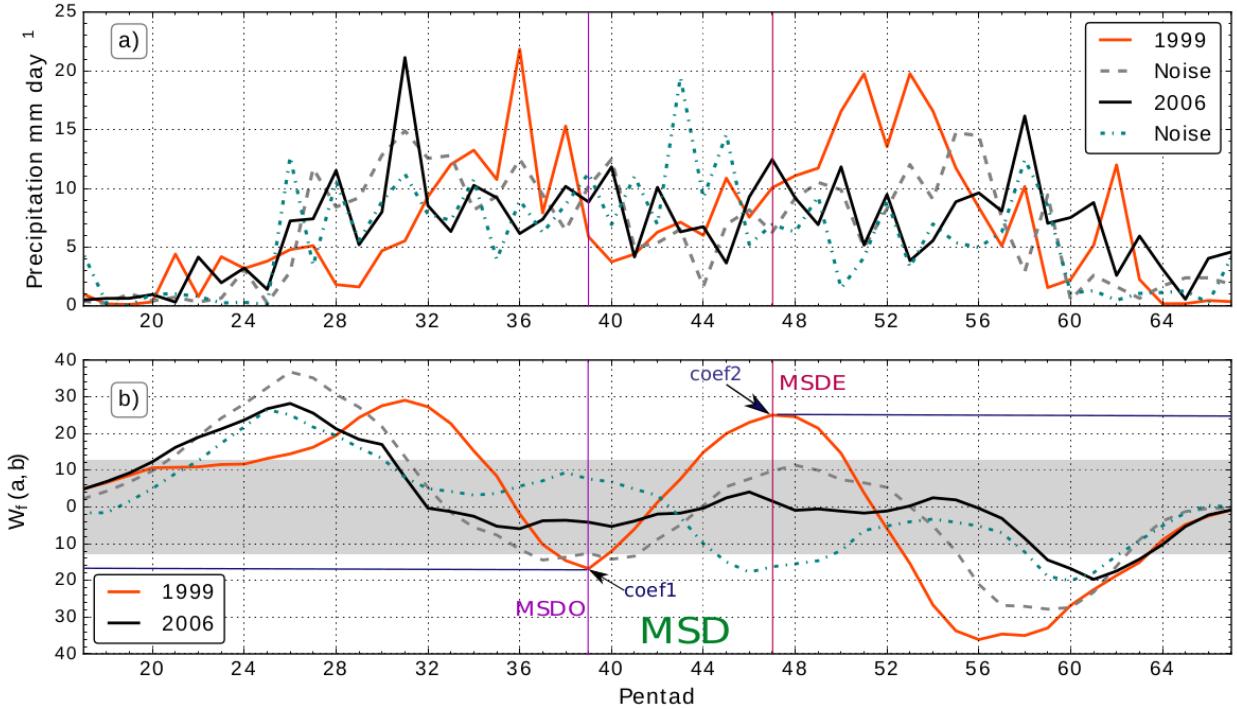

Figure 5.14: (a) Pentad-mean precipitation in two years of TRMM data: 1999 and 2006 and two randomly generated precipitation time series (see text). (b) Sum of the wavelet transforms of the time series in (a). The shaded region in gray in (b) corresponds to the interval between the first quantile of $coef1$ and the third quantile of $coef2$ of 10,000 random timeseries constructed with TRMM data. The onset (MSDO) and end (MSDE) of the relatively drier period, as well as the location and values of $coef1$ and $coef2$ for 1999 are labelled in (b).

follow a plateau, see for example the North and South American monsoons in Figure 4.9 in the previous chapter. However, a bimodal regime would show a notable decrease in precipitation in the middle of the rainy season, such that it cannot be explained by the inherent short-scale variability of rainfall.

This approach has two advantages. First, that the random time series impose a monsoon-like feature with a sharp wet-dry season contrast but secondly, the random selection in the wet season removes the possible signal of the MSD in the climatological rainfall. The random time series are then constructed by randomly drawing values at each pentad from the wet or dry season distributions of each dataset. Then, the WT method was used on 10,000 of these random-time series. This approach rendered a distribution of coefficients ($coef1$ and $coef2$) essentially representing the variability of the WT method applied to noise.

Figure 5.14 shows the pentad-mean time series from two years in the TRMM dataset,

and two randomly generated time series. The coefficients $coef1$ and $coef2$, illustrated in Figure 5.14b, measure the difference in precipitation between the first peak and the MSD period and the MSD and the second peak, respectively. The first quantile of $coef1$ and the third quantile of $coef2$ provide a measure of robustness for the observed $coef1$ and $coef2$. In other words, for a year to be classified as having a robust MSD signal, the resulting $coef1$ and $coef2$ of the WT procedure must be lower and higher, respectively, than those obtained for a random time series. The analysis of $coef1$ then determines the existence of a first-peak MSD type variability and $coef2$ determines the robustness of a possible second-peak for that year. By this procedure, a given year could fit into four categories:

- Canonical MSD: $coef1$ lower than the first quartile (25%) of random $coef1$ and $coef2$ higher than the third quartile (75%) of random $coef2$.
- 1st peak+MSD: $coef1$ lower than the first quartile of random $coef1$ but $coef2$ lower than the third quartile of random $coef2$. In other words, the second peak is not distinguishable from noise.
- 2nd peak only: $coef1$ higher than the first quartile of random $coef1$ but $coef2$ higher than the third quartile of random $coef2$. In other words, the second peak is distinguishable from noise, but there is no first-peak + MSD structure.
- No MSD: $coef1$ higher than the first quartile of random $coef1$ and $coef2$ lower than the third quartile of random $coef2$. In other words, the precipitation time series shows no robust signal of an MSD regime, with a first or second peak.

Figure 5.13 shows how separating years into these categories affects the pentad-mean seasonal cycle of precipitation in southern Mexico and Central America in four observational datasets. This figure also validates the above procedure as the WT method is able to robustly separate years into the different categories.

For each dataset we determine those grid-points showing a robust MSD. We use the method outlined above to construct the random time series for each grid-point and estimate the random values of $coef1$ and $coef2$, repeating the procedure 10,000 times. A given

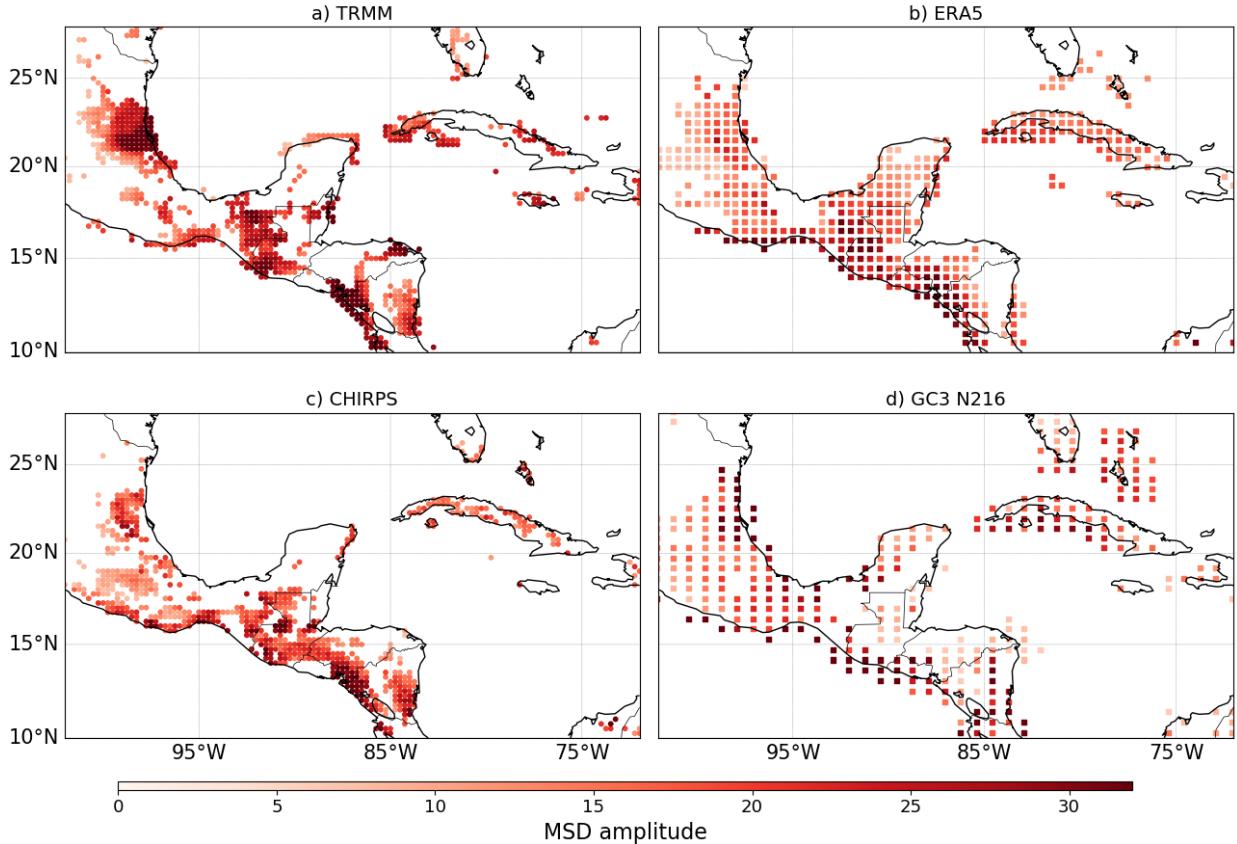

Figure 5.15: Grid points where the MSD is significantly different, i.e. outside the first and second quartiles of the random distribution, from noise (see section 3.3) for a) TRMM, b) ERA5, c) CHIRPS and d) GC3 N16-pi. The magnitude of the MSD, measured as $coef2 - coef1$ is shown in colour shading.

grid-point is diagnosed to have a robust MSD when the value of $coef2 - coef1$ is higher than the third quartile of the PDF of the random time series. The value of $coef2 - coef1$ is a measure of the magnitude of the MSD since $coef2$ measures the relative strength of the second-peak compared to the MSD and therefore positive in an MSD grid-point and $coef1$ compares how dry the MSD is relative to the first-peak and thus negative if an MSD regime is observed at that grid point.

Figure 5.15 shows the regions where the climatological rainfall shows a MSD signal that is distinguishable from noise, i.e., regions where the values of $coef2 - coef1$ exceed the third quartile of the distribution composited with random time series, as well as the magnitude of the MSD for the TRMM, ERA5, CHIRPS and the GC3 N216 piControl simulation. Cuba, western Central America and most of southern and central-eastern Mexico exhibit a robust

MSD signal. This map also shows that the strongest MSD signal is found on the western coast of northern Central America and northeastern Mexico. The high correspondence between the three observational datasets shows that the method is robust across datasets. These results agree well with previous studies on the spatial distribution of the MSD (Magaña et al., 1999; Perdigón-Morales et al., 2018; Anderson et al., 2019; Zhao and Zhang, 2021). In particular, the method is able to replicate the previously reported MSD signal in the Pacific Mexican coast and the stronger MSD signal in northeastern Mexico.

Figure 5.16 shows the spatial distribution of the mean onset and retreat pentads and the

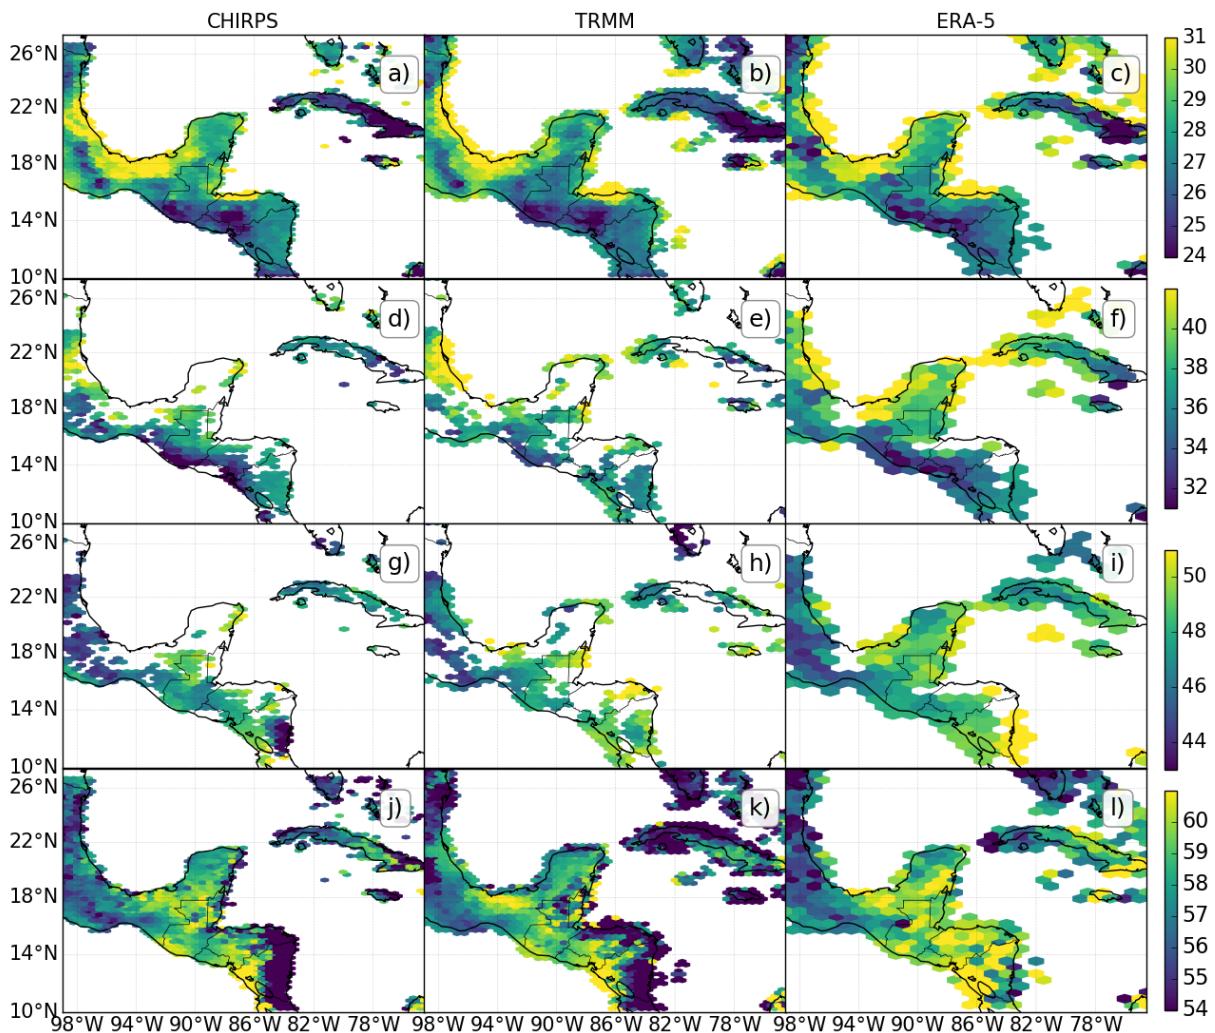

Figure 5.16: Spatial distribution of pentad dates of the timings of the summer rainfall season in the MSD region, showing (a-c) MO dates and (d-f) MSDO dates, (g-i) MSDE and (j-l) MR for (left) CHIRPS, (middle) TRMM and (right) ERA-5.

start and end of the MSD, in the grid-points where the signal is significant as in Fig. 5.15. The earliest rainfall onset is found on the western coast of southern Mexico, Guatemala and El Salvador, as well as in Cuba, at pentad 25, whereas onset in the Yucatan peninsula is found at pentad 28 and even later, around pentad 31, in the eastern states of Mexico. In contrast, the retreat date seems spatially more homogeneous as northern Central American has a mean retreat date around pentad 59 and central Mexico around pentad 54. The MSD coherently starts over the western coast of Guatemala and Chiapas around pentad 33. In contrast, the MSD on the eastern Mexican states of Veracruz and Campeche begins after pentad 40. The earliest MSD end (Figs. 5.16h-j) is found in central and northeastern Mexico, around pentad 42 whereas the MSD in Guatemala ends around pentad 48.

5.5 Summary and discussion

The assessment of the AMS in the MOHC submissions to CMIP6 in Chapter 4 lacked a robust analysis of the representation of the timings of the monsoon. The principal reason for this shortcoming was the lack of a robust, widespread method to diagnose onset and retreat dates in the various regions of the AMS with the various datasets available. This chapter aimed to address this issue by developing a new method to compute onset and retreat dates for the purpose of intercomparison between multiple observational and model data.

The novel method described in this chapter uses pentad-mean precipitation data to compute a wavelet transform over multiple temporal scales from which a set of coefficients and diagnostics are used to determine onset and retreat dates. The wavelet function used is the Haar wavelet, a wavelet typically used to find abrupt changes in signals. Onset is defined as the maximum of the sum of the coefficients of the wavelet transform computed over a range of temporal scales or dilations. These dilations were found to provide the best results in a range from 28 to 54 pentads. Monsoon retreat is similarly defined but uses the minimum of this sum of wavelet transform coefficients. The use of this method is illustrated using multiple observational datasets and climate model output. The method is compared to existing methods to find onset and retreat dates in three monsoon regions.

The method performs favourably to existing methods that use precipitation thresholds in the North American Monsoon, as shown by the anomalies of precipitation, wind and geopotential around the onset and retreat dates. The spatial distribution of monsoon onset and retreat in this region was found to be sensibly captured by the wavelet algorithm, illustrating the earlier onset in central-western Mexico and the later onset in northwestern Mexico, Arizona and New Mexico. The spatial distribution of onset and retreat dates was diagnosed to be very similar between the TRMM, CHIRPS and ERA5 datasets, which suggests that the method produces similar results in datasets with different resolutions and climatologies. These results confirm that these models reasonably simulate the seasonal cycle of precipitation in the North American monsoon. This result also suggests that the method is robust to be used at the grid-box scale, and not just for region-averaged time series.

The WT method also compares well to a hydrologically defined index (HOWI) in the Indian Monsoon, although the WT better captures the precipitation variations whilst HOWI betters captures changes to the moisture transport. However, the WT method is also able to capture strong differences in moisture transport around the onset and retreat dates, in both models and observations. The WT method obtains a later onset and retreat as compared to the HOWI index, which is possibly associated with a lag between the moisture transport about the Arabian Sea (as diagnosed by HOWI) and the precipitation over mainland India (as measured by the WT method). The spatial distribution of onset and retreat dates in the Indian Monsoon region, diagnosed using the WT method seems to be relatively consistent and coherent amongst the observational datasets, as the mean onset date in mainland India was found at pentad 32. Onset is earliest on the western coast of India and the onset date appears to be very homogeneous in central India.

The WT method was extended to characterise the timings and strength of the Midsummer Drought (MSD), using the same principle as for determining onset in the Indian monsoon, but computing the WT over smaller dilations around the onset and retreat dates. By using randomly-generated time series, the spatial distribution of grid-points displaying a robust MSD signal was found in Cuba, the northwestern coast of Central America and several regions of south and north-eastern Mexico. The MSD in southern Mexico and northern Central America is found to start around pentads 35 and 36 (last week of June) and end

around pentad 48 (mid-August) in most observational datasets and the ERA5 reanalysis. To our knowledge, this extension of the WT method provides one of the very few methods for characterising the MSD on sub-monthly scales.

The WT method is in many ways similar to the agronomical and threshold methods (e.g. Liebmann and Marengo, 2001; Moron and Robertson, 2014), as the implementation of the method uses a subjective determination of the dilation scales; these scales are comparable to the persistence and window parameters of the threshold methods. However, the WT method presented has three main advantages over most threshold methods. First, the method produces robust results for the Indian and North American monsoon of onset and retreat, and spatial distributions comparable to previous methods (Moron and Robertson, 2014) while not being subject to 'false hits' nor years without an identification of the onset and retreat dates. In other words, the method provides robust results without requiring further treatment of years with false hits or undetermined years.

The second advantage of the method is portability, or utility, as the method shows robust and consistent results for three observational datasets, a reanalysis and climate model experiments with varying climate forcing but without any constraint or treatment of the data beforehand and in three different regions with different seasonal cycles. In other words, this method is robust across datasets and regions. In contrast to rigid threshold techniques (e.g. Liebmann and Marengo, 2001), the identification of onset and retreat for each time series, e.g. at each grid-point, is based upon coherent temporal changes within each precipitation time series while not using parameters determined *a priori* specifically for a region. The WT method can then be used in any time series, regardless of the origin of the time series, without any further change or consideration than those established by the dilations scales determined in section 2.2.1. The portability of the method also means that the method can be implemented as a *local-scale* method applied at the grid-box scale for high-resolution datasets such as CHIRPS as well as for regional scales using area-averaged time series.

Third, and in contrast to typical threshold methods, the wavelet method can be applied to climate model output straightforward using the same configuration of dilation scales, a feature of the method that is illustrated by our analysis of several experiments using the Hadley Centre models. The treatment of the data does not require any normalisation or statistical

treatment even when used for grid-point time series for different regions or experiments with varying forcing where the seasonal cycle or total annual rainfall may change notably within the model time series. The method may be used for other purposes such as finding active and break phases of a monsoon, however, due to the constraints of the WT, the method cannot be used for forecasting purposes, or real-time identification of the onset and retreat.

This chapter provides the main tool for the following chapter, which aims to better understand the physical mechanisms behind the MSD, a question that would be difficult to address without the existence of a robust method for determining the timings of the MSD at the pentad-scale.

6

The Midsummer drought in the MOHC CMIP6 experiments

This chapter investigates the mechanisms associated with the bimodal seasonal cycle of precipitation, also known as Midsummer drought (MSD), of southern Mexico and Central America using CMIP6 experiments produced by the Met Office Hadley Centre. The chapter evaluates three theories for the MSD that exist in the literature: SST and cloud-radiative feedbacks, the double crossing of the solar declination angle and the moisture transport associated with the Caribbean Low-Level Jet (CLLJ).

6.1 Introduction

A bimodal signal in the climatological seasonal cycle of precipitation has been documented in several regions of southern Mexico, Central America and the Caribbean; most commonly referred to as Midsummer drought (MSD Mosiño and García, 1966; Magaña et al., 1999; Gamble et al., 2008; Perdigón-Morales et al., 2018; Zhao et al., 2020). Since the first observational descriptions of the MSD, research has aimed to understand the physical mechanisms that cause the two-peak structure of precipitation (e.g. Hastenrath, 1967; Magaña et al., 1999; Curtis, 2002; Herrera et al., 2015; Maldonado et al., 2017; Straffon

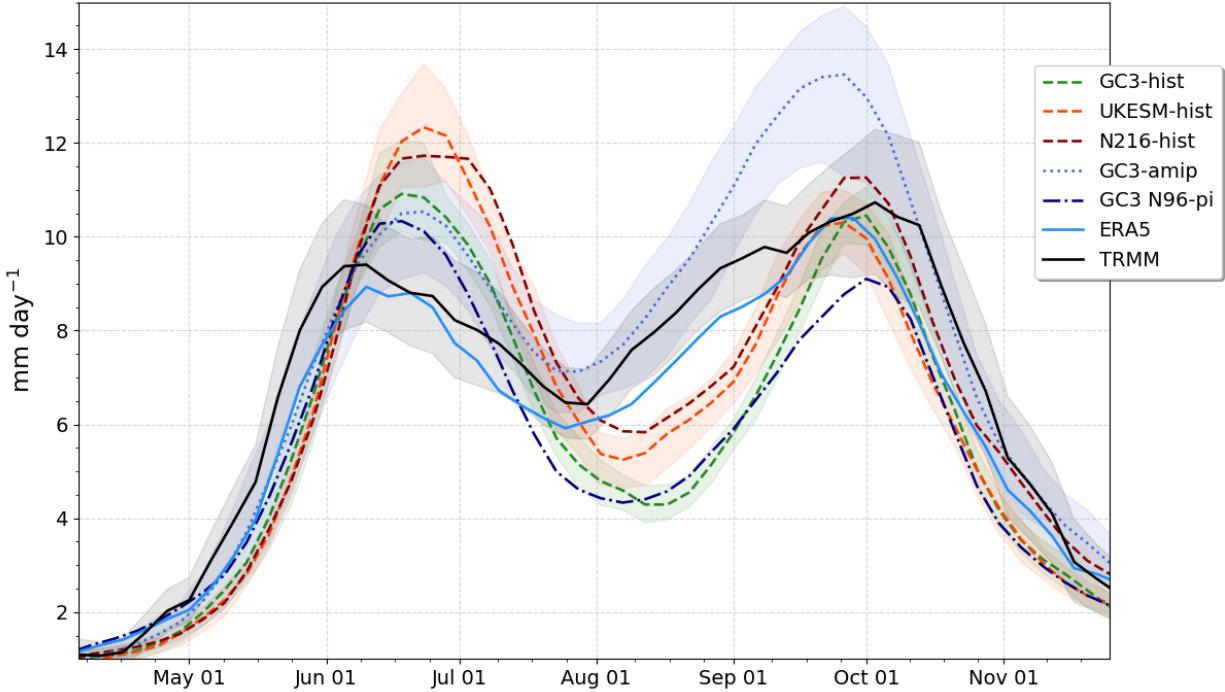

Figure 6.1: Pentad-mean precipitation in southern Mexico and northern Central America [95–86°W, 11–19°N]. The shading for the TRMM dataset is a measure of observational uncertainty obtained by bootstrapping the interannual variability whereas the shading for the CMIP6 experiments show the ensemble spread where multiple ensemble members were available.

et al., 2019; Perdigón-Morales et al., 2019; Zermeño-Díaz, 2019). Section 2.3 summarises the literature on the theories for mechanisms for the MSD and their limitations.

Moreover, most global climate models from the CMIP5 cohort struggle to reasonably reproduce the seasonal cycle of precipitation in the region (Rauscher et al., 2008; Ryu and Hayhoe, 2014) which has led other studies to use regional climate models to understand mechanisms and future projections (Fuentes-Franco et al., 2015; Cavazos et al., 2020). Less attention has been given as to why some GCMs reproduce or not the bimodal seasonal cycle; for instance, Ryu and Hayhoe (2014) only analysed how biases in large-scale features of CMIP3/5 models such as the North Atlantic Sub-Tropical High (NASH) could influence the representation of the MSD. Chapters 4 and 5 show that the CMIP6 MOHC simulations reproduce the timings and strength of the bimodal signal of precipitation with reasonable skill (Figure 6.1), albeit with a stronger first peak and a later onset of the MSD.

The lack of agreement in the literature on the leading mechanism for the bimodal seasonal

cycle of precipitation and the good representation of the spatial and temporal characteristics of the MSD in the MOHC CMIP6 experiments are the main motivation for this chapter. This chapter aims to increase our understanding of the physical mechanisms associated with the MSD of southern Mexico and northern Central America, also referred to as Mesoamerica, by diagnosing relevant processes that are represented in these MOHC CMIP6 experiments.

Three leading hypotheses (section 2.3) are investigated for the MSD of southern Mexico and Central America: the SST-cloud-radiative feedback proposed by Magaña et al. (1999), the solar declination angle hypothesis (Karnauskas et al., 2013) and the CLLJ as a modulator for moisture transport and convective activity in Mesoamerica (Herrera et al., 2015; Zermeño-Díaz, 2019). The main features of the three mechanisms are illustrated in Figure 6.2. The SST cloud-radiative feedback mechanism (Fig. 6.2a) proposes that the peaks and trough of precipitation in the seasonal cycle are a result of a similar seasonality in the East Pacific SSTs and surface humidity. During the first peak of precipitation, cloud radiative effects (CREs) block shortwave radiation from reaching the surface in addition to increased latent heat fluxes from the ocean to the atmosphere which cool the SSTs and lead to a decrease in convective activity and precipitation. During this drier period with less cloud cover, incoming shortwave increases again and raises East Pacific SSTs above 29°C and surface humidity leading to the second peak of precipitation.

The solar declination angle hypothesis (Fig. 6.2b) argues that total shortwave radiation absorption at the surface is the key element that controls the surface energy balance and the strongest control of the seasonal cycle of incoming shortwave is the solar declination angle. The total shortwave absorption by the surface modifies the surface moist static energy, specifically the surface moisture, which in this framework is the ultimate control of precipitation. In Central America, the solar declination angle crosses twice during the summer, once at the start and once at the end, and evidence by Karnauskas et al. (2013) suggests that precipitation follows the solar declination angle and surface moist static energy with a lag of a few weeks.

Finally, the third mechanism investigated in this chapter argues that the seasonal cycle of the CLLJ, possibly influenced by the seasonal variations to the NASH, modifies moisture transport in the region (Fig. 6.2c). Studies have noted that the increase in the jet strength

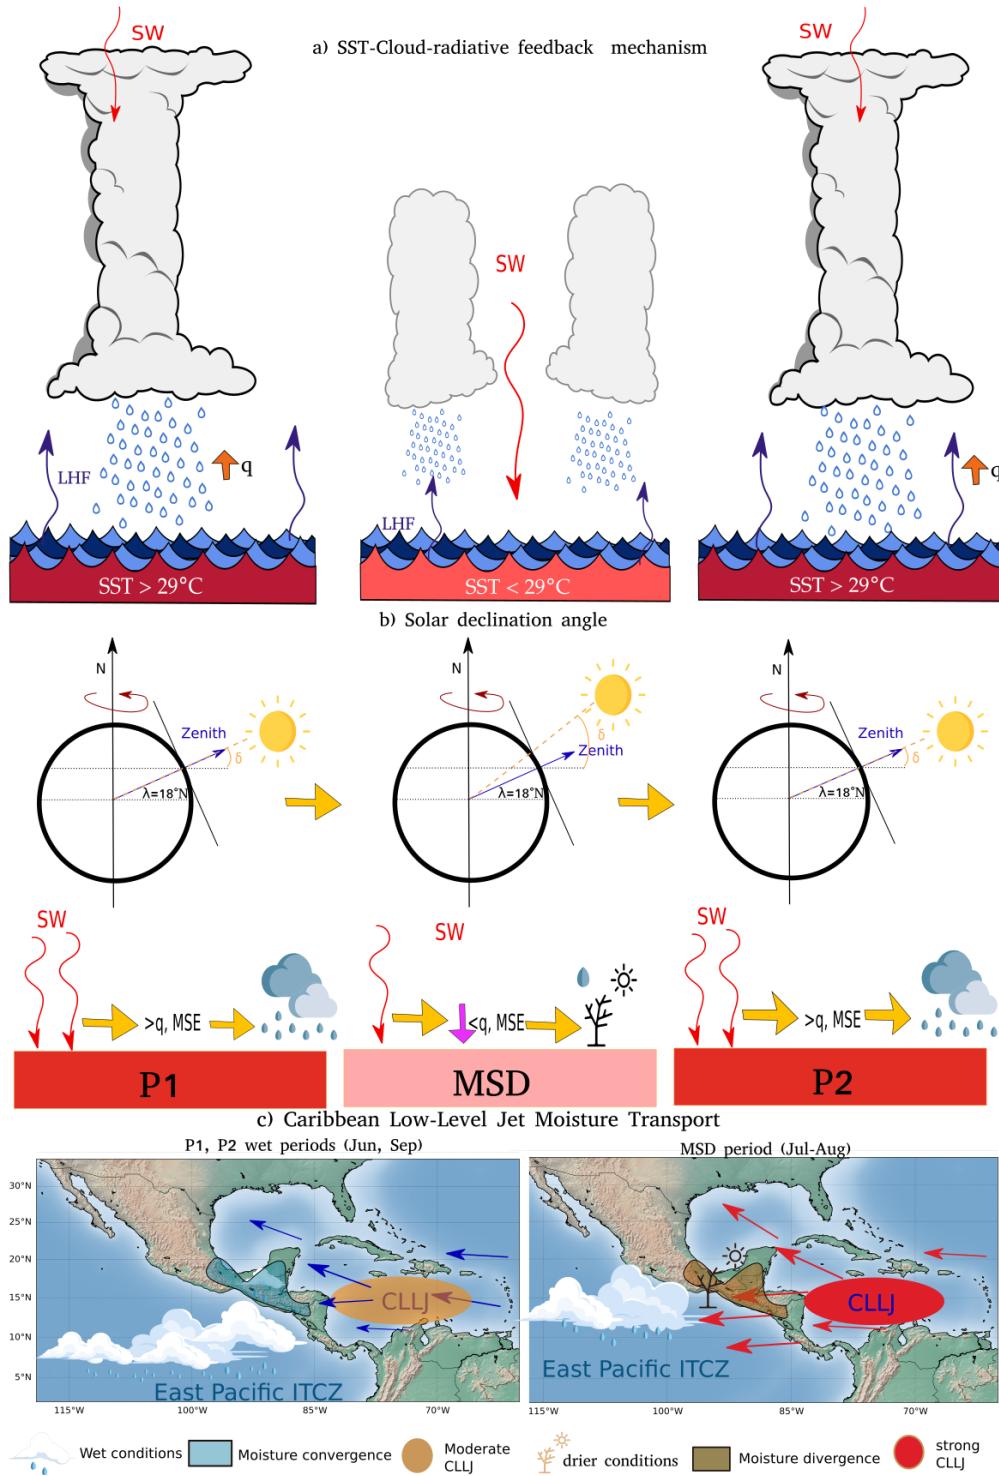

Figure 6.2: Schematic of the three mechanisms analysed in this chapter, a) the SST cloud-radiative mechanism, (b) the solar declination angle and (c) the moisture divergence mechanism driven by the CLLJ. In all panels, three stages of the MSD are represented (left) the first peak period, (middle) MSD and (right) the second peak period.

at the midsummer coincides with a reduction of rainfall over mainland. This argument appears more frequently in studies to explain the MSD of the Caribbean (e.g. Martinez et al., 2019), but suggestions have also been made that the CLLJ variations could control the total moisture transport over the continent (Herrera et al., 2015). Specifically, the hypothesis is that in July the strengthening of the CLLJ decreases the convergence of moisture over the continent and the total water content over western Central America, explaining the slight decrease in precipitation during the MSD period.

The remainder of this chapter is presented as follows. Section 2 describes the observational data and the CMIP6 experiments and summarises how the WT method is implemented to diagnose the timings of MSD. Section 3 evaluates the representation of the key features of the regional climate in the CMIP6 experiments and in ERA5. Then, the roles of the East Pacific SSTs (section 4), cloud-radiative effects and surface shortwave absorption (section 5) and the CLLJ and moisture transport (section 6) are investigated using composite and regression analysis. Finally, a short investigation of the MSD using the moist static energy budget is given in section 7. A summary and discussion is presented in the final section of this chapter.

6.2 Data and methods

6.2.1 Observations and reanalysis data

All the data used in this chapter are described in more detail in Chapter 3. This chapter uses the precipitation datasets of TRMM and CHIRPS. The remaining diagnostics are taken from ERA5 at the 0.75° resolution and for the period 1979-2019. ERA5 precipitation data is used throughout this chapter to compare against the models, and not observed datasets, because of two reasons. Firstly, observational (satellite or surface station) data of all diagnostics are not available on long periods at the daily resolutions required for this study, for example of the wind flow or moisture profiles over the ocean region. Secondly, ERA5 precipitation in the MSD region closely follows TRMM and CHIRPS (Fig. 6.1), and the previous chapter shows that ERA5 reasonably reproduces the mean timings for the MSD compared to TRMM and CHIRPS. Therefore, ERA5 can be compared to the simulations as another model; one that is more realistic as the reanalysis is partially driven

by the observed state of the atmosphere through the assimilations of radiosondes taken in the region as well as satellite data of various quantities (Hersbach et al., 2020).

6.2.2 CMIP6 data

This chapter uses the output from realizations of the HadGEM3 GC3.1 run at two resolutions at N96 and N216 and from UKESM1. These experiments are described in section 3.2.2 and summarised in Table 3.2. The main experiments used in this chapter are the pre-industrial control (piControl), AMIP, and historical experiments. The pre-industrial control experiments use a constant external forcing for the year 1850, and are relatively longer integrations (Menary et al., 2018), whereas the historical experiments use our best estimate of the time-varying aerosol and greenhouse gas emissions from 1850 to 2014 (Eyring et al., 2016; Andrews et al., 2020). The AMIP experiments use the same external forcing as the historical experiments but also "nudge" the SSTs using observational products, thereby decoupling the atmosphere from the ocean and removing SST biases (Eyring et al., 2016).

In addition to these deck experiments used in previous chapters, this chapter uses experiments from the Cloud-Feedback MIP (CFMIP) (Webb et al., 2017) and ScenarioMIP (O'Neill et al., 2016) activities of CMIP6 (see Table 3.2). The experiments from CFMIP are the GC3-amip lwoff in which longwave radiative effects are turned off and amip-p4K and amip-m4K in which the SSTs are increased and decreased 4 K, respectively, globally from the main amip experiment. The runs used from the ScenarioMIP are forced using the Shared Socioeconomic Pathways (SSPs): SSP1, SSP2 and SSP5 which correspond to Sustainability, Middle of the Road and Fossil-fuel development narratives, respectively (O'Neill et al., 2017). In these scenarios, global mean temperatures increase at the end of the 21st century, relative to pre-industrial levels, between 0.40 to 2.05°C, 1.27 and 3.00°C for SSP2 and 2.40 and 5.57°C for SSP5 (Tebaldi et al., 2021).

6.2.3 Determination of the timings of the MSD

Chapter 5 describes a wavelet transform (WT) method that can determine the timings of the MSD in observational gridded datasets, reanalysis and climate model precipitation time series. This chapter uses the WT method to determine the onset (MO) and retreat

(MR) of the monsoon rainy season, as well as the onset (MSDO) and end (MSDE) of the MSD. MO and MR are determined by the maximum and minimum sum of WT coefficients computed from a dilation scale vector ranging from 24 to 54 pentads. After MO and MR are determined, a second WT is computed with dilation scales from 10 to 24 pentads and the minimum sum of the WT coefficients corresponds to the onset of the MSD and the maximum to the end of the MSD (MSDE). Similarly, the timings of the first (P1) and second (P2) peaks of precipitation are determined from the results of the WT method: P1 is defined as the period between the MSDO and the preceding 4 pentads or 20 days, whereas the second peak is defined as the period between the date of MSDE and the subsequent 4 pentads.

An example of this separation of the MSD timings for each year is given in Figure 6.3, for precipitation observed from TRMM in 2017 over the study region. The area of study of this chapter is in southern Mexico and northwestern Central America (depicted in Figure 6.4) a region with strong and robust MSD signals (see Chapter 5). The WT method was applied to the TRMM, CHIRPS and ERA5 datasets and in the model precipitation time series area-averaged over the study region.

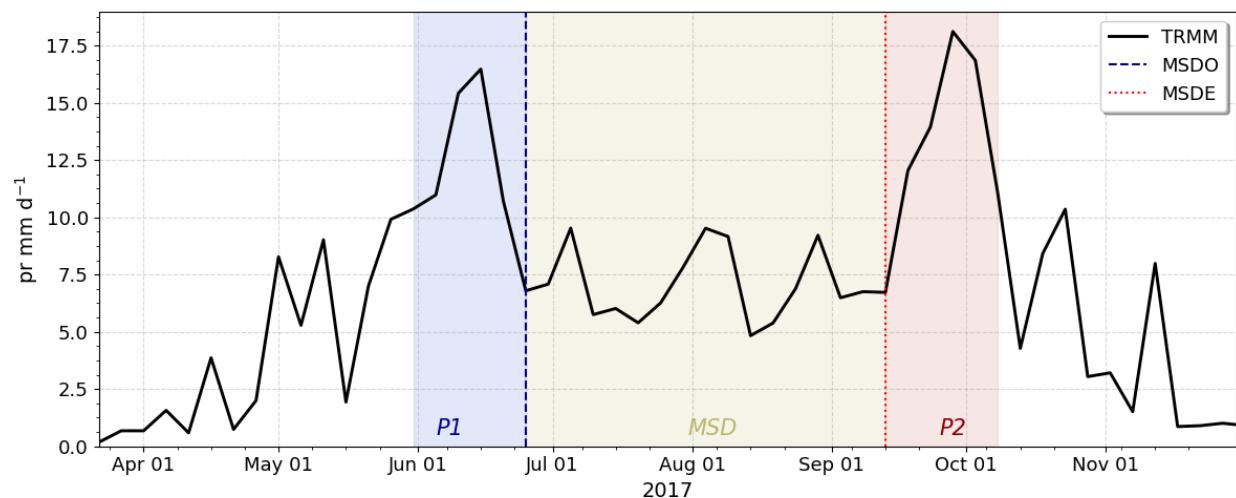

Figure 6.3: Pentad-mean precipitation averaged over the study region [95–86°W, 11–19°N] in the TRMM dataset for the summer of 2017. The timings of the onset (MSDO) and end (MSDE) of the MSD, as well as the first (P1) and second (P2) peak periods and the MSD periods are highlighted.

6.3 Climatological features

The seasonal cycle of precipitation in the MSD region (Figure 6.1) is reasonably well simulated by the CMIP6 experiments and by ERA5, as shown in previous chapters. The two-peak structure of the MSD is observed in TRMM and ERA5 as two precipitation maxima, the first peak found during early to mid-June and the second peak at the end of September, separated by a drier period that spans from late June to late August. The precipitation in ERA5 agrees well with the seasonal variation of TRMM and the mean rates during the first peak, the MSD and second peak periods.

The MSDO in the CMIP6 experiments is diagnosed one or two pentads after TRMM and ERA5 and the experiments show a stronger variation of precipitation between the first

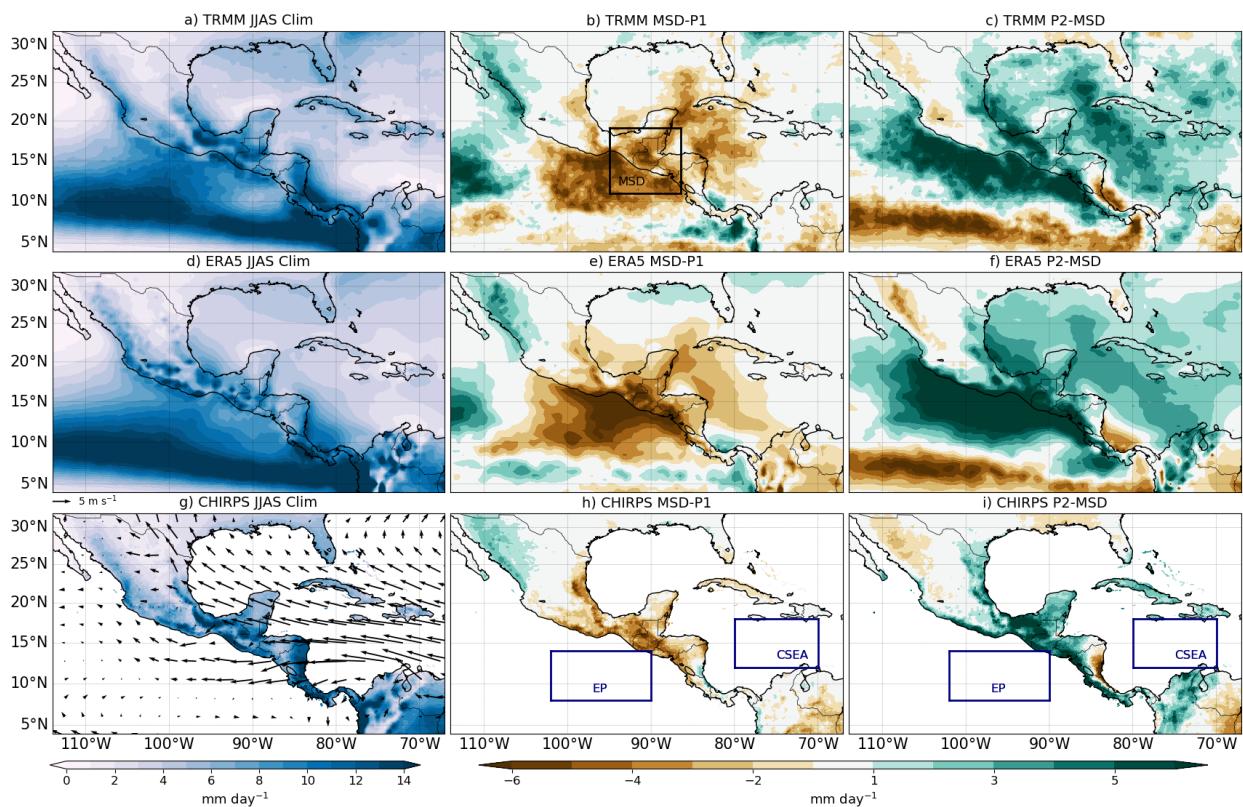

Figure 6.4: (a, d, g) Climatological JJAS rainfall and the difference between (b, e, h) the midsummer drought and the first peak (MSD-P1) periods and (c, f, i) between the second peak and the midsummer drought (P2-MSD) periods for (a-c) TRMM, (d-f) ERA5 and (g-i) CHIRPS. The climatological low-level winds (at 850 hPa) for JJAS in ERA5 are shown in c). The boxes in panels b, h and i show the definitions of the MSD, EP and CSEA regions that are used throughout this chapter.

peak and the MSD. A noteworthy feature is that most experiments simulate a drier MSD period but wetter peak periods. In particular, the pre-industrial control experiments show a higher magnitude of precipitation during the first peak and the MSD period whereas GC3-amip experiments are characterized by a wetter second peak.

The climatological distribution of precipitation and the temporal differences within the MSD timings in ERA5 agrees well with TRMM and CHIRPS (Figure 6.4). ERA5 reasonably captures the climatology of precipitation over land over the East Pacific ITCZ. The biases of JJAS-mean precipitation in ERA5 (Figure 6.5) are positive over the East Pacific Ocean and western Mexico, and negative over land in southern Mexico and Central America.

The patterns of the MSD-P1 and P2-MSD differences in ERA5 (Fig. 6.4) also agree well with TRMM. The precipitation differences associated with the MSD timings within the box in Figure 6.4b extend well outside the study region comprising the easternmost Pacific Ocean, the entrance to the Gulf of Mexico and western Caribbean Sea, particularly in the P2-MSD panel. The interannual variability of mean boreal summer rainfall, and P1 and P2 magnitudes between ERA5, TRMM and CHIRPS are also very similar (not shown). This means that ERA5 may be used to investigate what processes best explain the interannual variability of precipitation of the reanalysis, specifically, what factors modulate the variations of the P1-MSD from one year to the next.

The simulations (Figure 6.6) have important biases in the magnitude of the precipitation in the East Pacific ITCZ with a positive bias of 3-6 mm day⁻¹ as well as a dry bias over

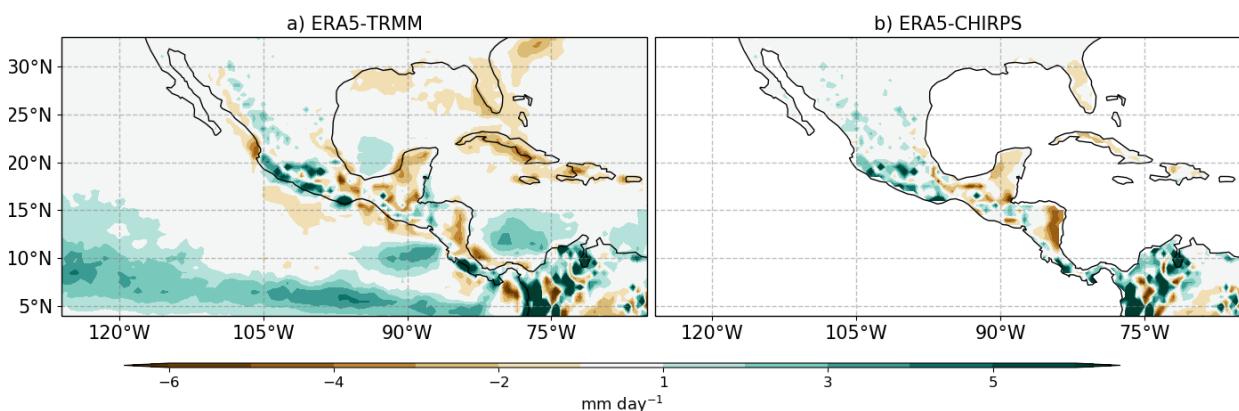

Figure 6.5: (a, b) JJAS precipitation biases in ERA5 when compared to (a) TRMM and (b) CHIRPS.

southern Mexico and Central America, as shown in chapter 4. These biases are much larger in the simulations than in ERA5. The simulations capture the spatial patterns associated with the MSD stages, characterised by the highest differences found on the west coast of southern Mexico and northwestern Central America. In agreement with ERA5 and TRMM, the precipitation differences in the MSD region in the simulations are always opposite to that of the North American monsoon region, e.g., in Figures 6.4 and 6.6 the North American monsoon is wetter when the dry period begins in the MSD regions.

The mean rainfall observed in the three periods (P1, P2 and the MSD) in the simulations varies notably between experiments with different configurations and with external forcing (Figure 6.7). The scatter of the first and second peak and the MSD mean rainfall rates show that the mean precipitation rate at each stage is not necessarily linearly related to another, i.e., a larger magnitude of the first peak of precipitation does not imply a wetter or drier

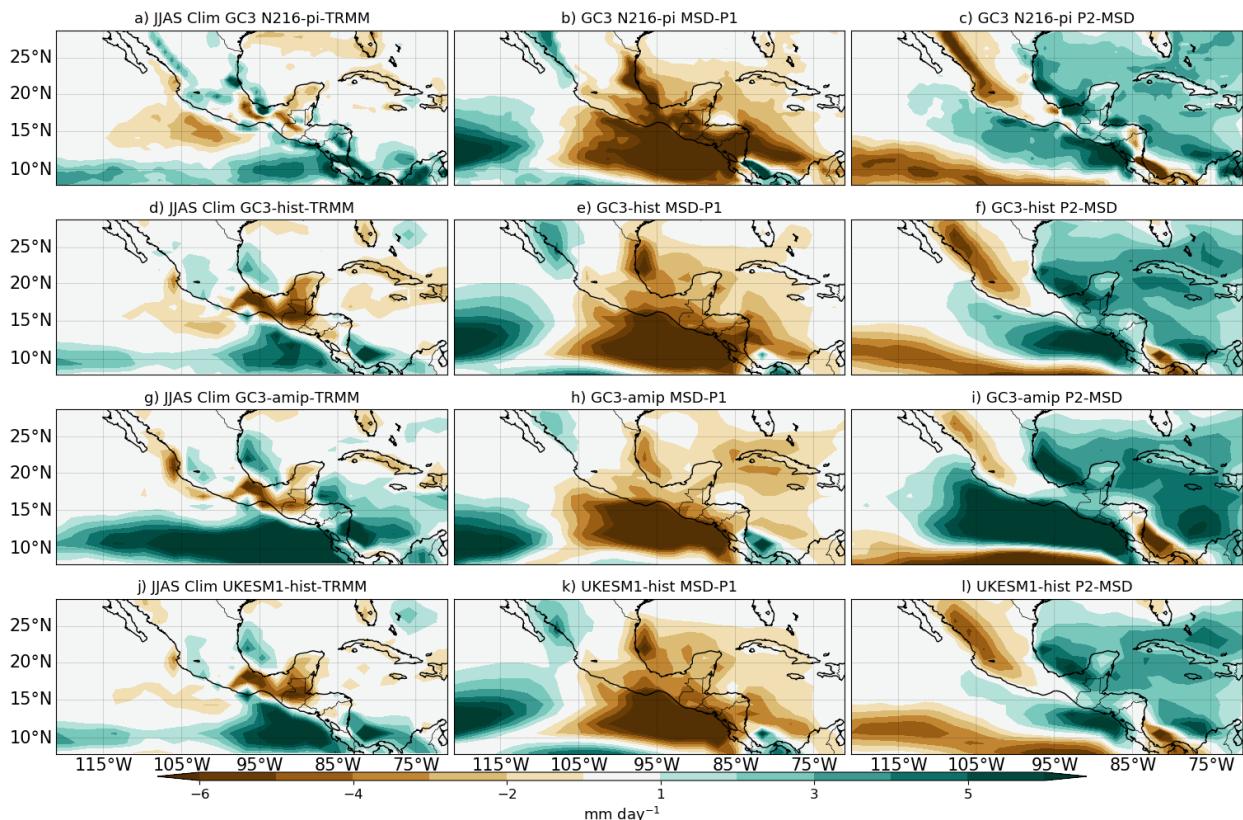

Figure 6.6: (a, d, g, j) JJAS model bias compared to TRMM and the difference between (b, e, h, k) the midsummer drought and the first peak periods and (c, f, i, l) between the second peak and the midsummer drought periods for four different simulations.

MSD period. The atmosphere-only runs, GC3-amip, are a good example of this behaviour as the mean rainfall during P1 is roughly the same as in the rest of the simulations but the mean rainfall during the MSD is slightly larger than in the rest of the simulations.

The magnitude of the first decrease in rainfall (MSD-P1) and the late-summer increase (P2-MSD) also show a significant spread amongst experiments (Figs. 6.7c-d), which also suggest that there is only a modest relationship between the magnitude of the MSD and the magnitudes of the two peaks of precipitation in these simulations. The scatter of ERA5 in all panels is notably close to that of TRMM and CHIRPS, which is further evidence that

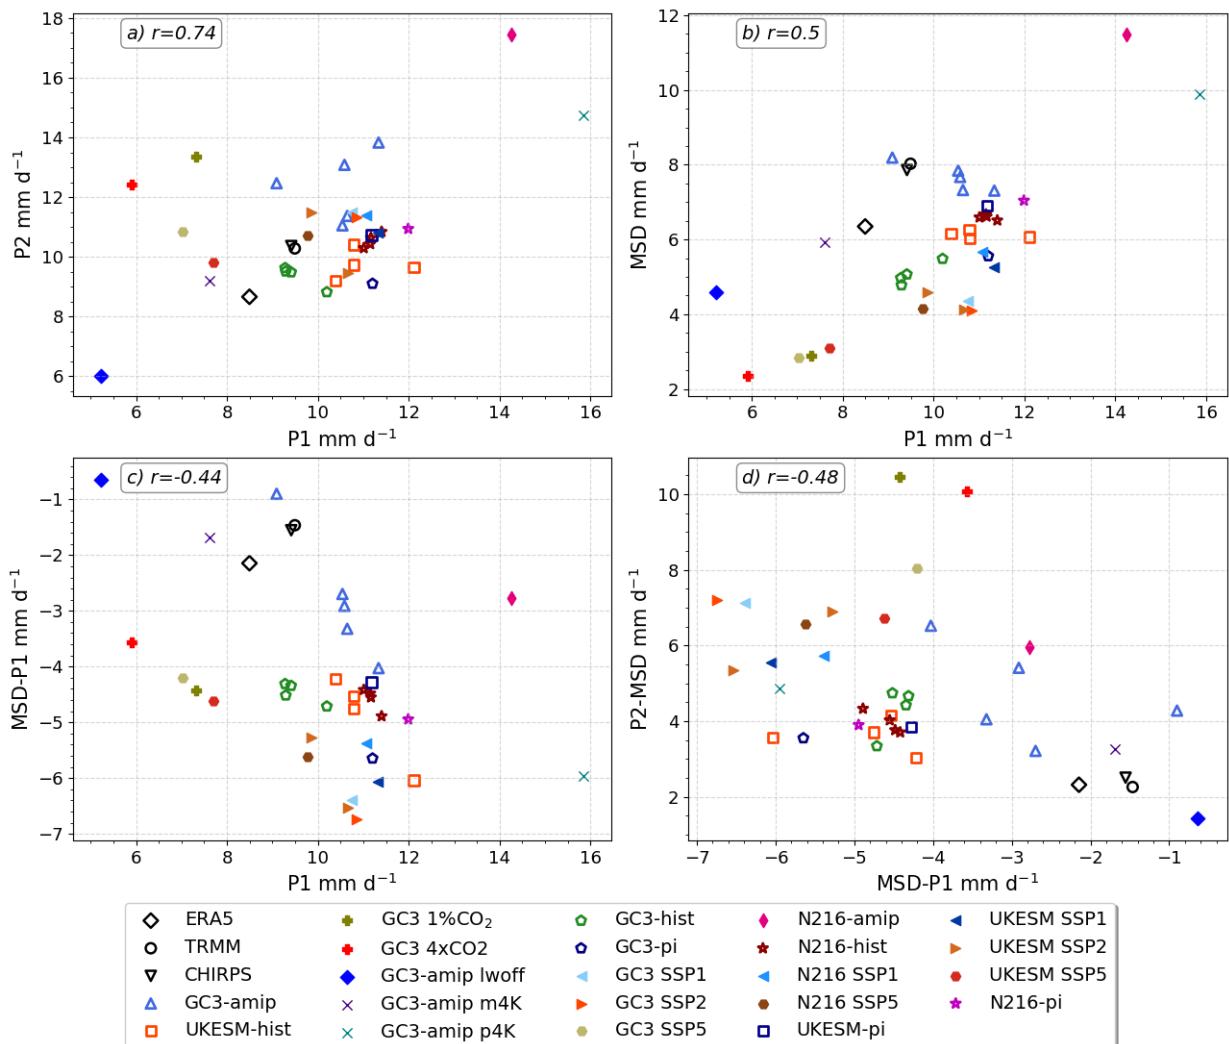

Figure 6.7: (a, b) Scatter plots of the mean values of precipitation [mm day⁻¹] for TRMM, ERA5, CHIRPS and the CMIP6 experiments (see 6.2.2) during the first peak (P1), the MSD and the second peak (P2) periods and (c, d) the precipitation differences between the three periods. The region used for this averages is illustrated in Figure 6.4.

the timings and strength of the MSD is well represented by this reanalysis. In contrast, the medium-resolution atmosphere-only run (N216-amip) shows the highest bias in precipitation throughout the three stages of the wet season.

This result is noteworthy because this configuration uses a higher resolution than GC3 N96 and is forced by observed SSTs, yet the simulation cannot capture the observed precipitation rates and is strikingly the worst simulation overall. One explanation for this result is that in the low-resolution simulations there are notable dry biases over land (Figs 6.6) and wet biases over the ocean, and the medium-resolution simulation improves the dry bias over land more so than the wet bias over the ocean leading to an overall increase of the bias over the whole region.

The outgoing long-wave radiation (OLR) and vertical velocity (ω at 500 hPa) differences associated with the MSD were computed using the WT method for each dataset (Figure 6.8). These composite results confirm that the MSD is not a local-scale feature but convective activity varies coherently in neighbouring regions. From the first peak period to the MSD, OLR and ω , increase in the easternmost Pacific, southern Mexico and northern Central America and extend into the Caribbean islands and Sea; because ω is defined as $\omega = DP/Dt$ these positive anomalies are indicative of weaker ascent.

In contrast, two regions show opposite responses to the MSD. A region several degrees west into the East Pacific Ocean (125°W) and another region north of the study region, i.e., the North American monsoon region, show signs of negative OLR and ω anomalies, in the MSD-P1 panels. These negative anomalies are indicative that, simultaneously to the onset of the MSD, convection is observed stronger and deeper in the North American Monsoon region and in the Pacific region west of the continent. The OLR and ω variations associated with the end of the MSD show a relatively opposite picture to the MSD-P1 differences. Note that several of these features have been described previously by Herrera et al. (2015), who argues that ascending and descending anomalies in the MSD are closely related to the 125°W East Pacific region.

The literature suggests that a number of climatological features of the region play key roles for the MSD (Section 2.3). These climate features include the seasonal cycle of the East Pacific (EP) SSTs, the Caribbean Sea SSTs, the EP zonal wind flow and the CLLJ

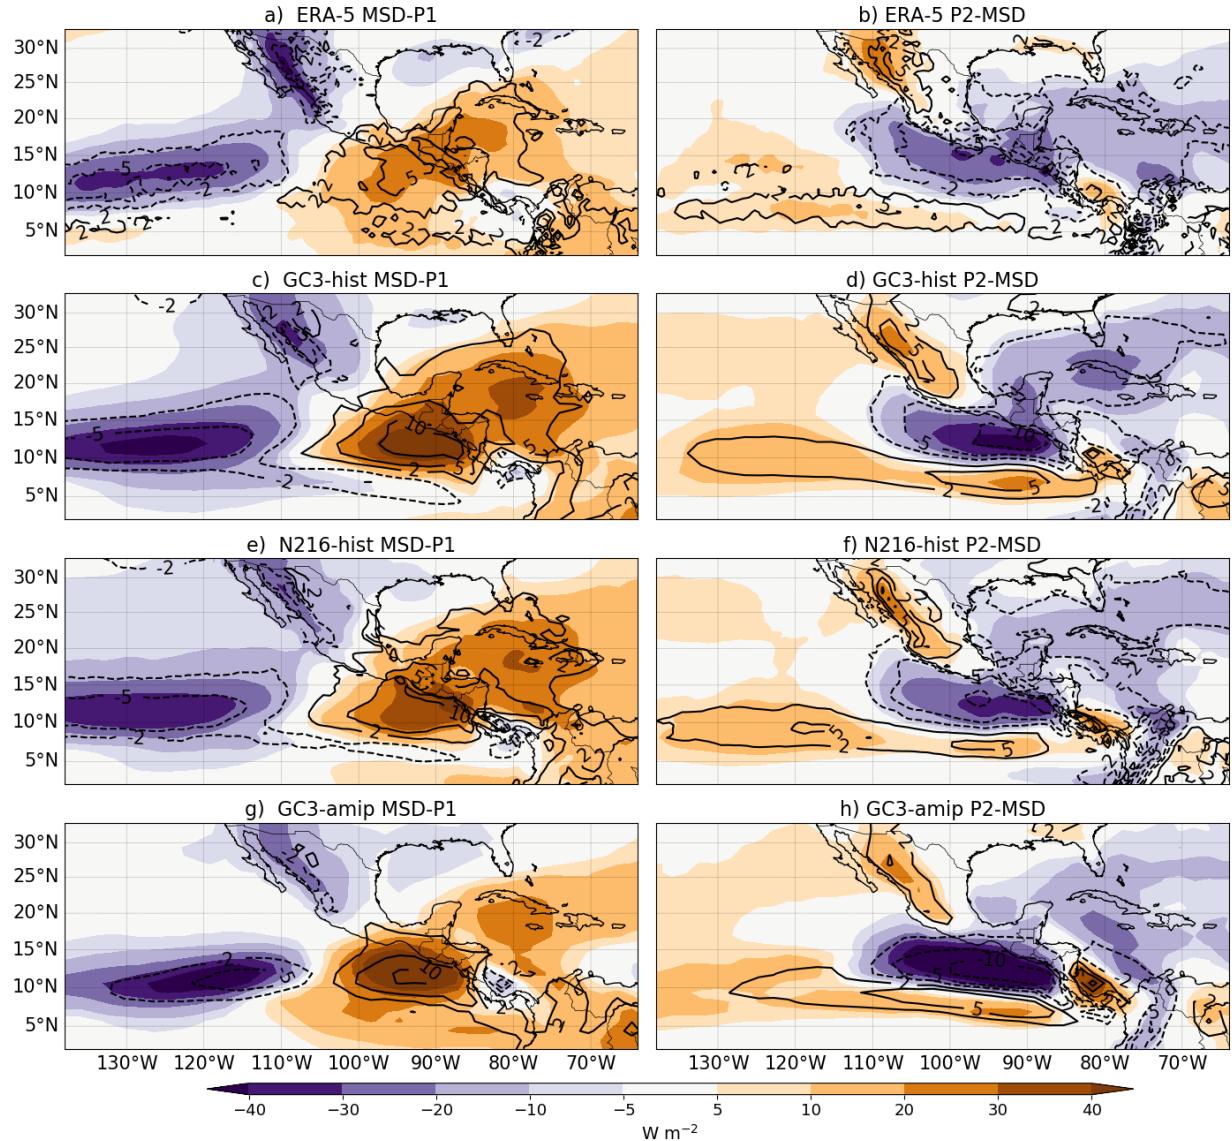

Figure 6.8: Outgoing long-wave radiation (OLR) [W m^{-2}] (shaded) and ω 500-hPa [$10^{-2} \text{ Pa s}^{-1}$] (line contours) differences between the MSD and first peak and the second peak and MSD.

(Magaña et al., 1999; Amador, 2008; Herrera et al., 2015; Straffon et al., 2019; García-Martínez and Bollasina, 2020). The seasonal cycle of these features in ERA5 and the simulations (Figure 6.9) shows that the models are able to replicate the seasonal variations of the SSTs and the zonal wind flow of the region.

The seasonal cycle of EP SSTs (Figure 6.9a) show that the maximum SSTs are found in late May, prior to the first peak of precipitation in Mesoamerica. In contrast, the Caribbean SSTs peak in early fall, about five months later, during late September. After the peak

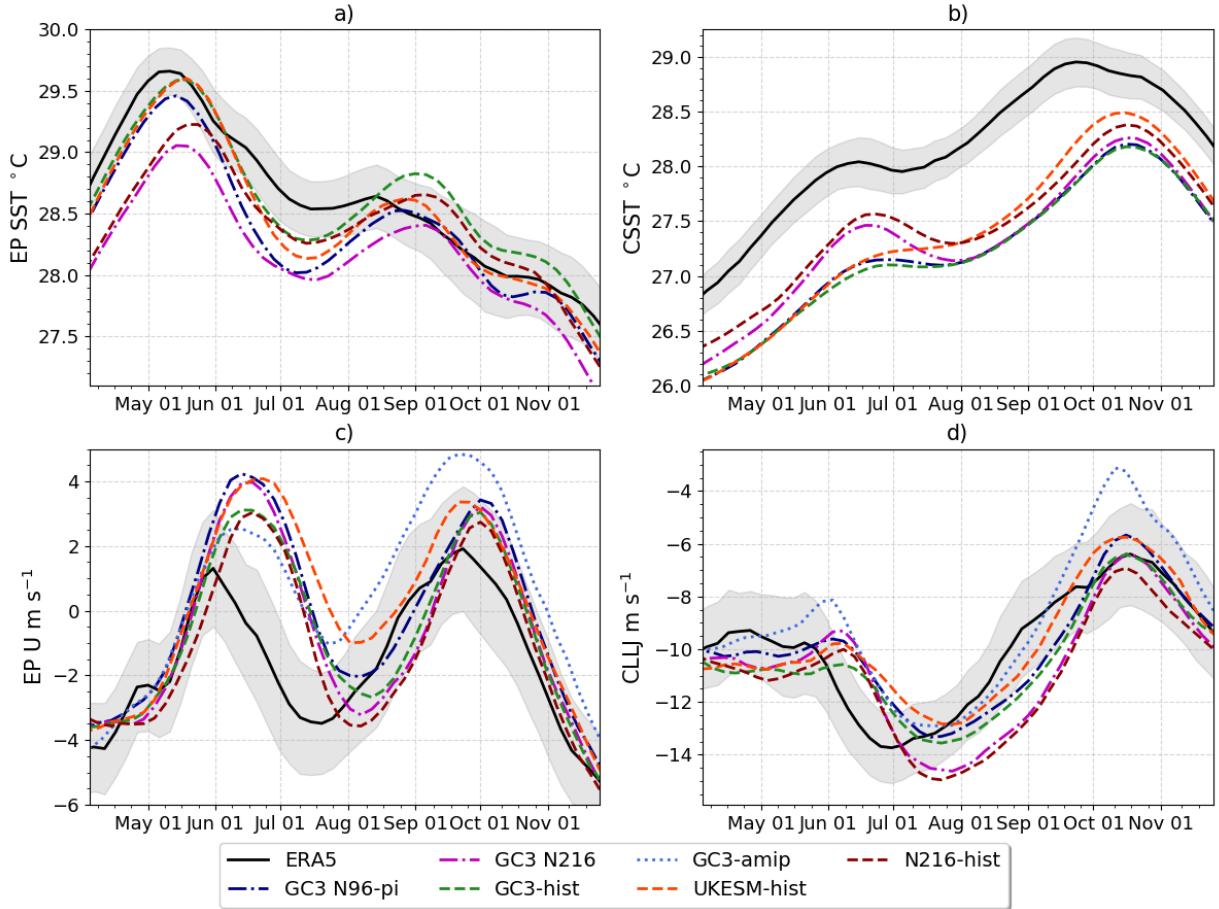

Figure 6.9: Pentad-mean seasonal march of the (a, b) SSTs [$^{\circ}\text{C}$] and (c, d) the low-level (925-hPa) zonal wind flow [m s^{-1}] in (a, c) the easternmost equatorial Pacific and (b, d) the Caribbean Sea. The transparent shading is as in Figure 6.1. The regions used for EP and CSEA averages are illustrated in Figure 6.4h.

SST period in the EP, SSTs decrease to a local minimum found in July both for ERA5 and the simulations. The models show a cold bias in the SSTs in both regions, but this bias is most pronounced in the Caribbean Sea.

The low-level wind flow in the EP shows a bimodal seasonal cycle in ERA5 and the simulations (Fig. 6.9c). The easterly flow in the EP during the spring becomes weaker turning westerly at the end of May and reaching a local maximum in early June in ERA5 and mid-June in the simulations. This local maximum then decreases during June and early July as the zonal wind becomes easterly again. The easterly flow peaks in mid July in ERA5 and two to three weeks later in the simulations. The strength of this easterly flow magnitude is more different between experiments during July and August than in other months. After the

easterly flow peaks in the midsummer, the zonal wind becomes westerly again peaking at the end of September in both ERA5 and simulations. This seasonality of the zonal wind in the EP is similar to the seasonal cycle of precipitation in the region in the models and simulations.

The CLLJ seasonal cycle (Figure 6.9d) is reasonably replicated by the simulations, compared to ERA5, although the peak strength of the CLLJ, which is found during the last week of June in ERA5, is delayed in the simulations by about three weeks, as the simulated CLLJ peaks in mid-July in all the simulations. The simulations follow closely the evolution of the CLLJ in late summer and fall, except for a notable bias in GC3-amip in Oct-Nov characterised by a weaker than observed CLLJ.

6.4 The role of East Pacific SSTs

The EP SSTs are a key element of mechanism proposed by Magaña et al. (1999), which argues that the EP SSTs, surface moisture, cloud radiative effects and surface fluxes are part of a feedback mechanism that explains the two peak structure of the MSD. A key prediction of this mechanism is that EP SSTs, surface moisture and turbulent fluxes exhibit a bimodal seasonal cycle in which EP SSTs and surface fluxes decrease during the first peak period and increase during the Midsummer drought period. In other words, this hypothesis predicts that the seasonal cycle of EP SSTs should be similar to the evolution of precipitation but out-of-phase, with the SSTs leading the precipitation. This section aims to evaluate these predictions for ERA5 and for the CMIP6 experiments.

According to the feedback mechanism, the EP SSTs cool down during or slightly prior to the onset of the MSD and then increase during the MSD period which then enhances precipitation and causes the second peak in late summer. However, in ERA5 the EP SSTs only very slightly increase during the MSD (Jul-Aug) and cool notably in late August and September in synchrony with the second peak in deep convection and precipitation (Figs. 6.1 and 6.9a). In the models, there is indeed a second peak in EP SSTs in late summer found in early September and therefore nearly synchronous to the second peak of precipitation. While EP SSTs clearly lead precipitation in May-June, the SST-precipitation relationship in mid and late summer is less obvious. In the models, the second peak of

SSTs is nearly synchronous to the second peak in precipitation, which seems to contrast with the predictions of the SST-radiative-convective feedback mechanism.

In order to better understand the relationship between EP SSTs and precipitation over the MSD region, the WT method is used to composite SSTs and surface humidity in the P1, MSD and P2 periods. The spatial distribution of SST and surface humidity changes associated with the MSD (Figure 6.10) suggest that the EP SSTs south of 10°N cool slightly between the P1 and MSD periods, meanwhile the Gulf of California and the northern eastern

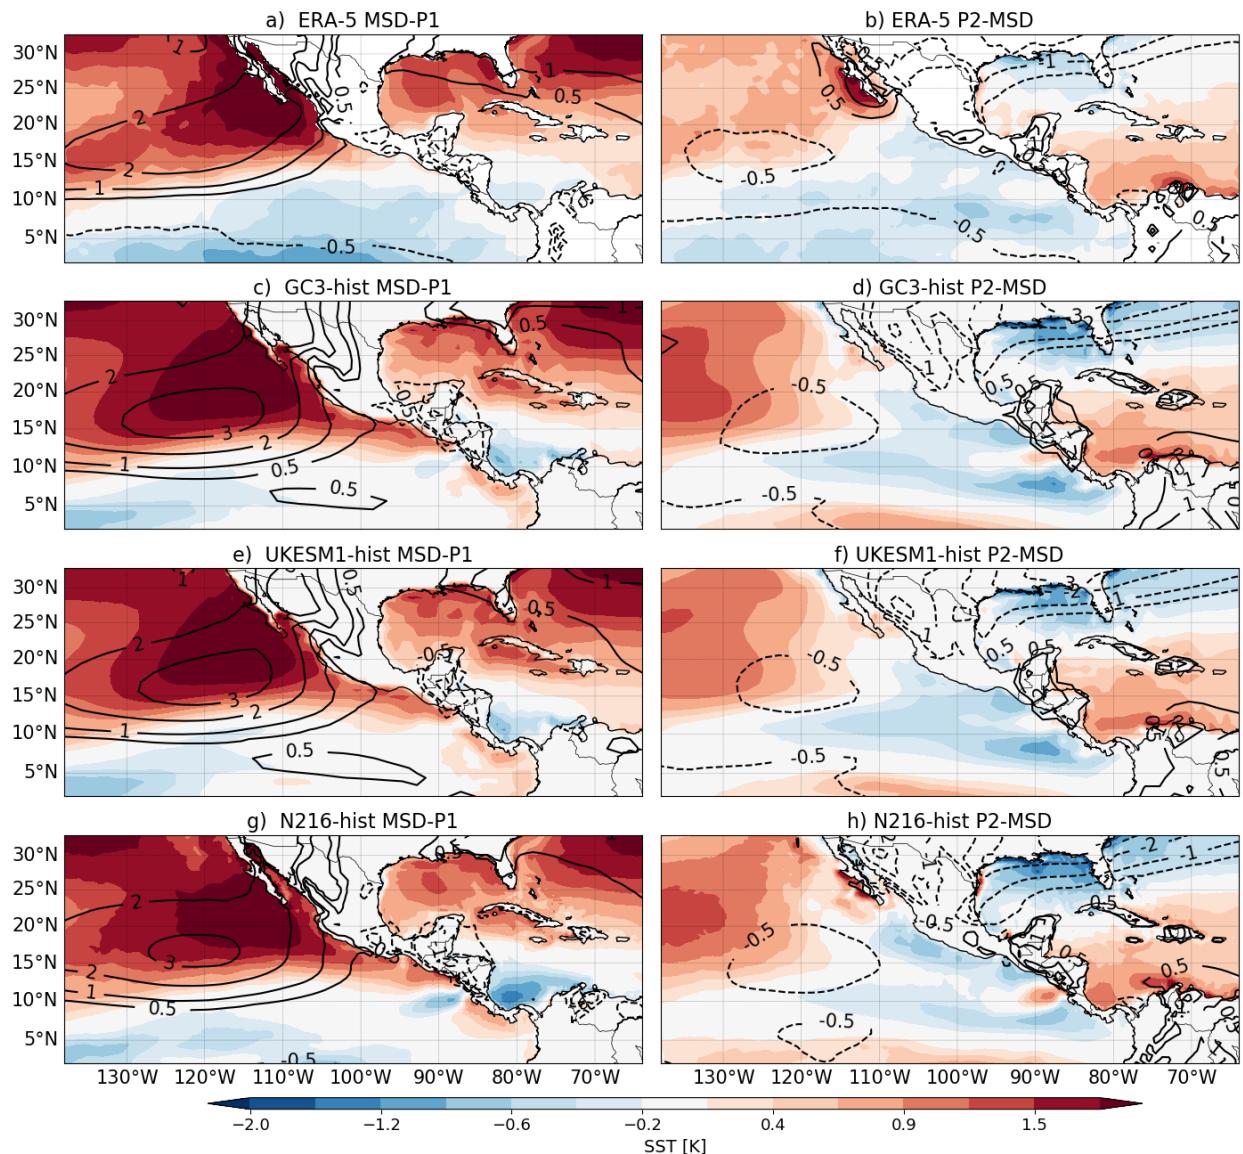

Figure 6.10: As in Figure 6.8 but the anomalies are shown for SSTs [K] (contours) and surface humidity [g kg^{-1}] (line-contours).

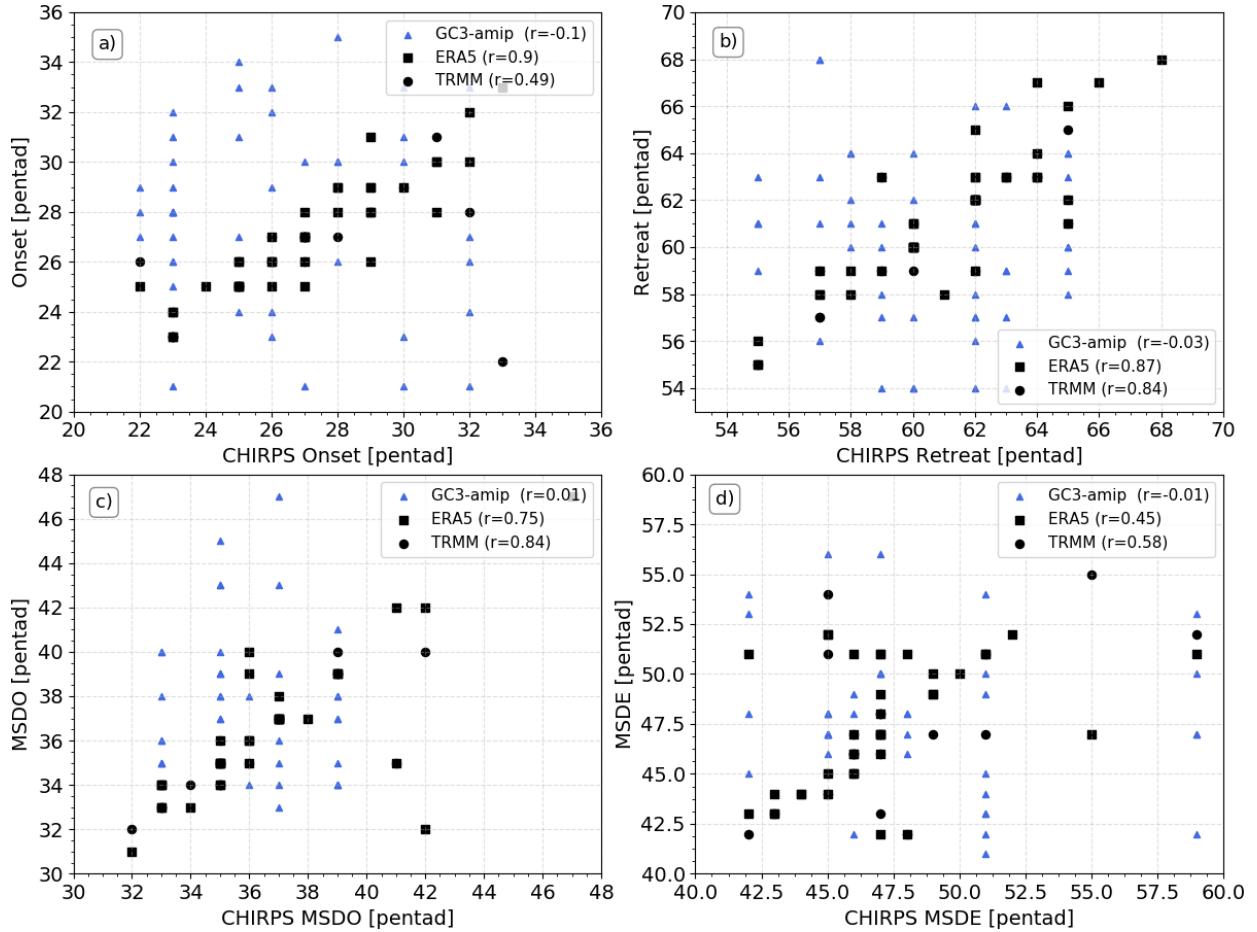

Figure 6.11: Scatterplots of the pentads diagnosed by the WT method as the dates of (a) monsoon onset (MO), (b) monsoon retreat (MR), (c) MSDO and (d) MSDE where the results of the CHIRPS dataset, on the x-axis, are compared with ERA5, TRMM and the GC3-amip simulation, on the y-axis. The legend shows the Pearson r coefficient for each comparison.

Pacific significantly warms. At the end of the MSD (P2-MSD), the EP SSTs decrease in both ERA5 and the simulations. The P2-MSD panels show that the Caribbean SSTs increase, as Caribbean SSTs peak at the end of the summer (Fig. 6.9b).

The historical simulations generally agree with the composite differences of ERA5, with no appreciable warming in the EP region in the MSD-P1 panels, and cooling in the EP and the Gulf of Mexico and warming in the Caribbean Sea in the P2-MSD panels. These results suggest that while the seasonal cycle of EP SSTs show a bimodal signal, when the timings of the MSD in each year of each simulation are examined more closely using the WT method, the EP SSTs do not synchronously warm during or after the MSD, contradicting the radiative-convective feedback mechanism.

Another element of the convective-radiative feedback mechanism is that the SST variability would force changes to the surface humidity and surface humidity would modify precipitation. The surface humidity in the EP and MSD regions, however, is unchanged (less than 0.5 g kg^{-1}) during the various stages of the MSD (Figure 6.10), even though precipitation varies notably during these periods. Instead, the greatest variations in surface humidity are observed west of Baja California and in the North American Monsoon region, both from the P1 to the MSD and from the MSD to the P2 periods. The surface humidity variations in the simulations also agree well with those of ERA5 and are very similar amongst the realizations.

If the EP SSTs play a dominant role in the timings and strength of the MSD, as implied previously (Magaña et al., 1999; Magaña and Caetano, 2005; Herrera et al., 2015), then the simulations with imposed SSTs taken from observations, e.g., the GC3-amip experiment, may be further explored to evaluate the links between SSTs and the timings or strength of the MSD. A scatter plot of the dates (pentads) of the MO, MR, MSDO and MSDE (Figure 6.11) for matching years between the CHIRPS dataset and TRMM, ERA5 and the five ensemble members of GC3-amip shows that the timings of the MSD in GC3-amip are unrelated to CHIRPS and ERA5. The timings from ERA5 agree very well with the CHIRPS and TRMM datasets. This evidence would suggest that the SSTs forcing the model in GC3-amip are not the dominant factor controlling the timings of the MSD in these atmosphere-only runs.

Alternatively, the interannual variability in ERA5 and the differences amongst the MOHC CMIP6 experiments may be further explored to understand whether differences in EP SSTs are related to changes of precipitation in the MSD region. For this purpose, composite differences between the P1, MSD and P2 periods were computed for each variable for each year in each dataset and then averaged to provide a mean value that relates changes in precipitation to different diagnostics in different stages of the rainy season. These results are presented in scatter plots that aim to diagnose emergent properties and physical relationships that explain the different representations of the MSD. **In this way we examine how each mechanism is able to explain the interannual variability of precipitation in ERA5 by comparing how each variable can explain the year-to-year differences in P1, P2 and MSD precipitation rates.**

The mean difference in SSTs (Figure 6.12a) between the P1 and the MSD periods indicate cooling of the EP for ERA5 associated with the precipitation reduction. In contrast,

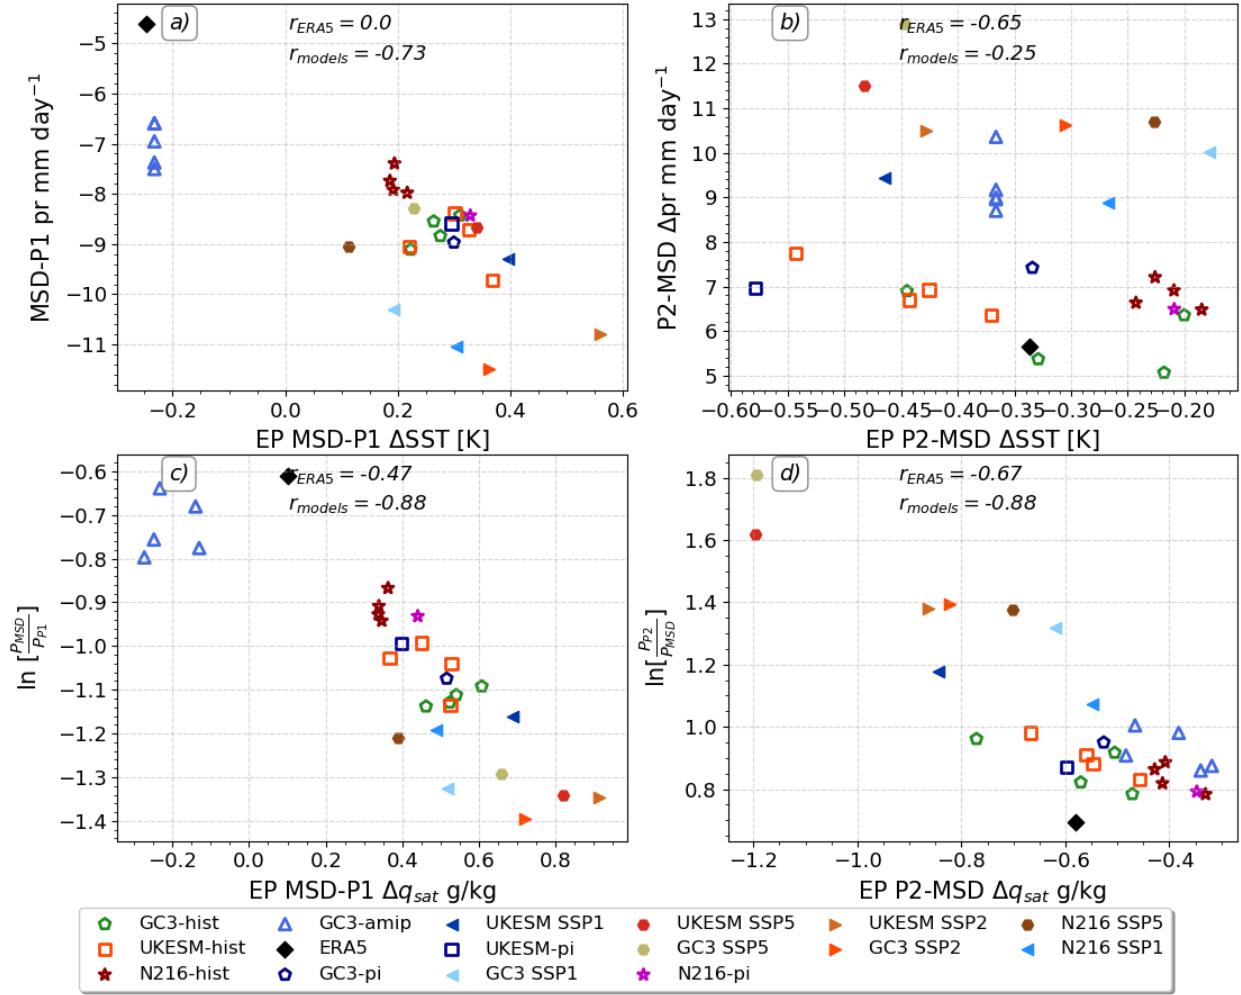

Figure 6.12: Scatterplots of the mean changes in the East Pacific (a, b) sea-surface temperatures (SSTs) and (c, d) surface saturation specific humidity q_{sat} in the x-axis with respect to precipitation variations in the MSD region on the y-axis for the (a, c) MSD-P1 and (b, d) P2-MSD periods. The correlation coefficient of the interannual spread in ERA5 and the multi-experiment correlation coefficient are shown in each panel. Only the mean values of ERA5 are plotted, but the correlation coefficients were calculated for the inter-annual variability of the 40-yr period in the reanalysis.

the coupled model simulations show a positive SST difference (warming) and a greater precipitation reduction from the P1 to the MSD period. The slight warming signal in the MSD-P1 difference (Figure 6.12a) in the coupled-model experiments suggests that in the models as precipitation decreases during the MSD, the EP SSTs warm by 0.2 K.

During the second peak, the EP SSTs cool (Figure 6.12b) associated with a positive increase in precipitation, suggesting an inverse relationship between EP SSTs and precipitation. However, the relationship does not seem to explain the inter-experiment spread or the

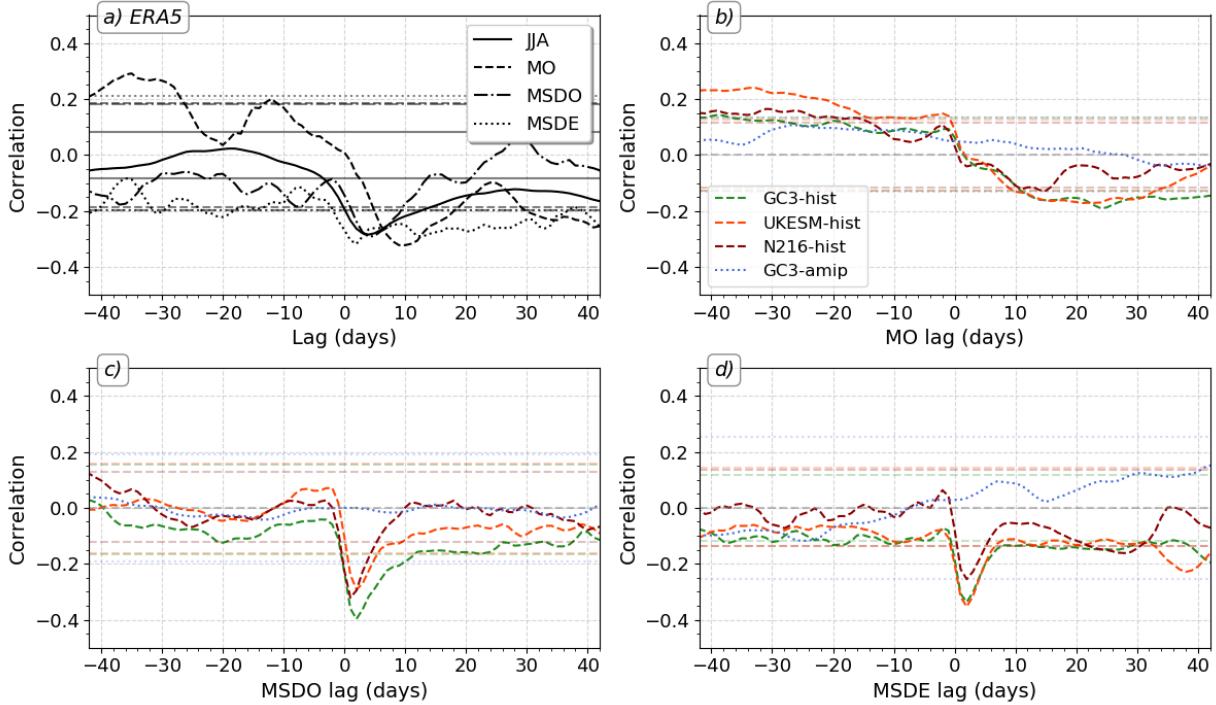

Figure 6.13: Lagged correlations between East Pacific SSTs and precipitation in the MSD region for (a) ERA-5 where the lag 0 date was used in four different ways: first, all the boreal summer JJAS SSTs and precipitation pairings, then lag 0 represents the monsoon onset (MO), MSD onset (MSDO) and MSDE dates. (b-d) as in (a) but for the simulations where the correlations are computed with the SST-precipitation timeseries lagged with respect to the b) monsoon onset date, the c) MSDO date and the d) MSDE date.

inter-annual variability in ERA5 as the correlation coefficients are low and not significant, i.e., a stronger second peak is not associated with a cooler EP SSTs in late summer.

Furthermore, evidence shows that the surface saturation specific humidity q_{sat} , which measures the maximum moisture that a parcel can hold, provides a strong link between precipitation and SSTs on seasonal time-scales over tropical oceans (Yang et al., 2019; Good et al., 2021). For these reasons, Figure 6.12 also shows the relationship between the saturation specific humidity at the surface and precipitation. The temporal changes to q_{sat} associated with the MSD timings (Figure 6.12c,d) are not positively related to changes in the precipitation over the MSD region. Although the inter-annual variability of q_{sat} changes during the MSD-P1 period in ERA5 shows a positive correlation, the mean changes to q_{sat} during this stage are very small compared to the differences in the experiments and, furthermore, the simulations shows an opposite relationship (negative correlation).

For the P2-MSD differences, there is a negative correlation for both ERA5 and the experiments, which means that the strongest second peaks of precipitation are associated with cooler SSTs. A more direct relationship was examined between the EP q_{sat} and EP pr . This analysis (not shown) resulted in a weaker (and negative) relationship in both regions between q_{sat} which suggests that changes to q_{sat} are not key to explain the variability of precipitation.

The previous results have analysed synchronous changes between the EP SSTs, surface humidity, q_{sat} and precipitation over the MSD region, but these relationships may exist with some lags and as suggested by the radiative-convective feedback mechanism, the SSTs should be leading precipitation. Lag-lead correlations (Fig. 6.13) of the EP SSTs and the precipitation in the MSD region show that only during monsoon onset are these two fields significantly positively correlated at lags of \approx -35 days in ERA5 and -40 to -20 days in the historical experiments.

In ERA5, the correlation for all the boreal summer (JJAS) sample is only significant for the SSTs leading precipitation region for negative lags from 30 to 40 days and is only significant (negative correlation) at positive lags at lag +5 days, indicative of an inverse SST-precipitation relationship where the SSTs follow precipitation. In the models (Fig. 6.13b-d), very similar results are found where significant positive correlations at negative lags, indicative of SSTs leading precipitation, are only found for the MO panel, whereas for MSDO and MSDE panels, the correlations are only significant at positive lags and for negative correlations, indicative of the precipitation leading the SSTs on the scale of 3-5 days and SSTs decreasing with increased precipitation.

This section investigated the radiative-convective feedback hypothesis by Magaña et al. (1999). Results in this section show that in observations, the EP SSTs do not exhibit a double-peak seasonal cycle, so the second peak of precipitation over the MSD region cannot be driven by a second peak in EP SSTs in late summer. Furthermore, evidence shows that the variations of precipitation during the midsummer are not statistically related to variations in EP SSTs in ERA5 or in the CMIP6 simulations, contradicting the main arguments of this hypothesis.

6.5 The role of cloud-radiative effects

The mechanisms proposed by Magaña et al. (1999) and Karnauskas et al. (2013) suggest that the net shortwave energy absorbed by the surface is key in the driving mechanism of the MSD. Magaña et al. (1999) argue that tall convective clouds influence the net shortwave (SW) flux at the surface and suggest that the cloud-radiative effects (CREs) experience seasonal changes that occur at the same as the MSD and are linked to the bimodal signal of precipitation. In turn, Karnauskas et al. (2013) argue that the seasonal march of solar insolation determined by the solar declination angle controls the net SW absorbed by the surface and this absorption of SW energy modulates the seasonal cycle of the surface energy balance and of precipitation. This section evaluates the predictions of these theories concerning CRE and the SW absorbed by the surface.

CREs are coupled to the tropical circulation (Bony et al., 2004; Webb et al., 2017) and influence the timing and strength of monsoons (Guo et al., 2015; Byrne and Zanna, 2020). The longwave (LW) CRE play an important role in the convective heating and moistening of the tropical atmospheric column whereas the SW CRE controls the surface absorption of energy (Allan, 2011). These studies motivate an investigation of the relationships between CRE, and the timing and strength of the MSD. The surface cloud radiative effect (CRE_{surf}) is computed from daily-mean fields following Allan (2011), as the sum of the LW and SW CREs, i.e.:

$$\begin{aligned} \text{CRE}_{surf} &= \text{LWC}\text{RE}_{surf} + \text{SWC}\text{RE}_{surf} \\ &= \text{LDS} - \text{LUS} - (\text{LDS}_{cs} - \text{LUS}_{cs}) + \text{SDS} - \text{SUS} - (\text{SDS}_{cs} - \text{SUS}_{cs}), \end{aligned} \quad (6.1)$$

where the fluxes are depicted as long-wave (L) or short-wave (S) and downwelling (D) or upwelling (U) at the surface (S) and the subscript $_{cs}$ denotes under clear-sky conditions. The long-wave upwelling at the surface (LUS) virtually cancels with the LUS_{cs} because the long-wave emission from the surface is minimally dependent on the presence of clouds (Allan, 2011). The net CRE at the surface is then given by:

$$\text{CRE}_{surf} = \text{LDS} - \text{LDS}_{cs} + \text{SDS} - \text{SUS} - \text{SDS}_{cs} + \text{SUS}_{cs}. \quad (6.2)$$

The CRE_{surf} during P1, MSD and P2 periods (Fig. 6.14) is negative and the minimum values are found in the East Pacific ITCZ region. The differences between the MSD timings closely follow the precipitation changes during these periods as the minimum CRE in the EP and the Mesoamerican region is found during the two peaks of precipitation with a weaker CRE over the Mesoamerican region and nearby basins during the MSD. The smallest CRE is found over the Baja California Peninsula. The results of the two historical experiments closely follow the results of ERA5, and the only notable difference is that the CREs are generally stronger in GC3-hist than in N216-hist.

The comparison of the individual contributions of the SW and LW surface CREs show that the dominant term in the EP and Mesoamerican regions is the SW term (Fig. 6.15). The negative SW CRE is strongest in the EP ITCZ region and the pattern of SW CRE varies temporally in similar fashion to the net CRE, i.e., in the MSD region, the SW term is notably larger ($<-90 \text{ W m}^{-2}$) during the two peak periods of precipitation than during

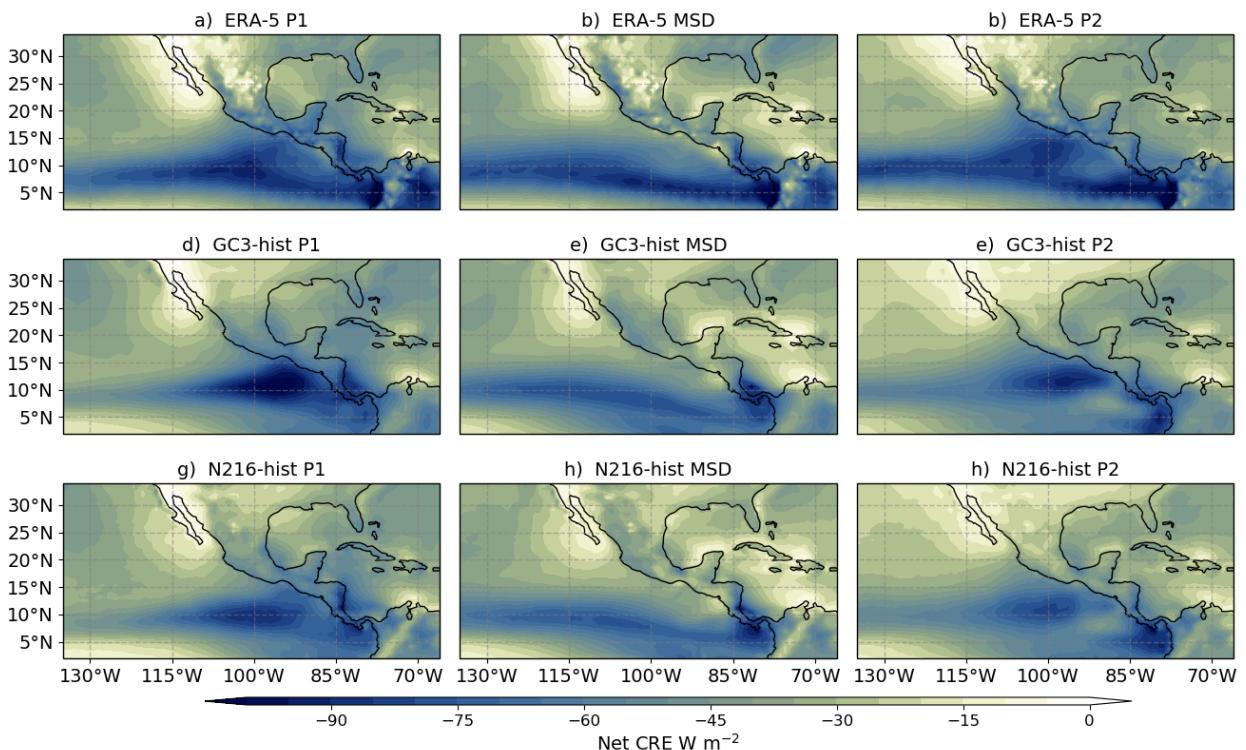

Figure 6.14: Composite mean net CRE at the surface [W m^{-2}] during the periods of onset of the MSD, the MSD and the end of the MSD for (a-c) ERA5, and the ensemble mean of (d-f) GC3-hist and (g-h) N216-hist.

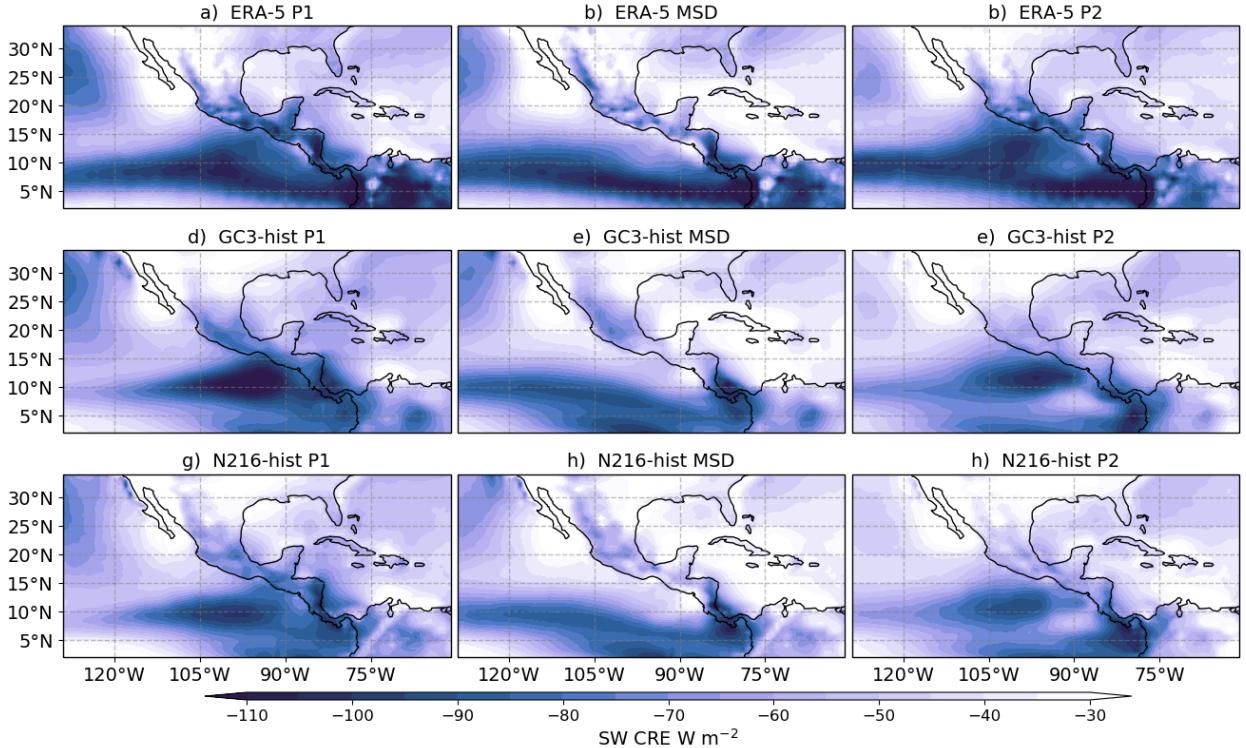

Figure 6.15: As in Fig. 6.14 but for the short-wave radiative effect.

the MSD. In the historical experiments, the SW CRE is strongest in the EP ITCZ region and the SW CRE over the MSD region varies notably in the three stages of the rainy season. In contrast, the LW term (not shown), is generally smaller in magnitude than the SW term and is largest over land and in the ocean west of the California. Over the EP and CSEA regions, the LW term shows very small horizontal gradients, indicative of fairly weak horizontal gradients in the LW effect of clouds.

These composites depict how the spatial distribution of the CRE synchronously varies with the MSD, but how these terms actually within the season in the MSD region is not obvious. The seasonal cycles of the SW, LW and net CREs (Figure 6.16a-c) show bimodal signals characterized by stronger CREs during the two peak periods during June and September and a relative minimum in between found in late July in ERA5 and early August in the simulations. The simulations reasonably simulate the magnitude of the net and SW CRE during the early summer season but overestimate the decrease in the net SW and LW CRE during the midsummer, very likely associated with the underestimation of precipitation over this same period (Figure 6.1).

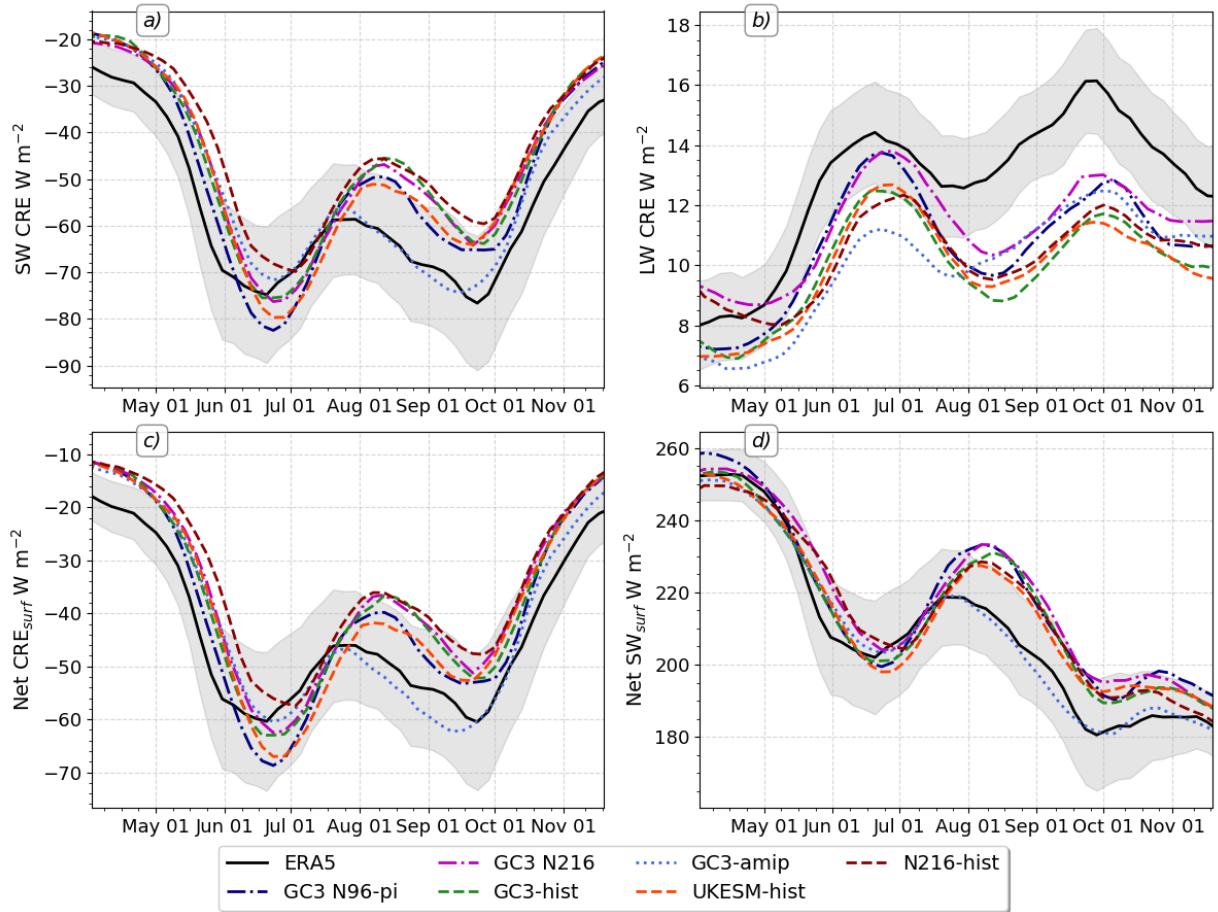

Figure 6.16: Pentad-mean seasonal cycle of the (a) SW and (b) LW CREs, (c) the net CRE, and (d) the net SW at the surface, signed positive to indicate surface absorption of SW radiation.

Regardless of CREs, according to Magaña et al. (1999) and Karnauskas et al. (2013), the net SW (the difference between upwelling and downwelling shortwave fluxes) at the surface should also have a bimodal seasonal cycle. In both ERA5 and the simulations, the net SW (Figure 6.16d) seasonal cycle is characterized by a first peak in late May, which coincides with the peak in East Pacific SSTs. This peak in surface SW is followed by a local minimum during June which is followed by a secondary increase in July in ERA5 and in August in the simulations. After this second local maximum, there is another sharp decrease of net SW at the end of the summer, which coincides with the second peak of precipitation, which agrees with previous hypotheses.

The spatial distribution of changes to the net SW at the surface (Figure 6.17) show that from the first peak to the MSD there is a positive difference in net SW, indicative of more

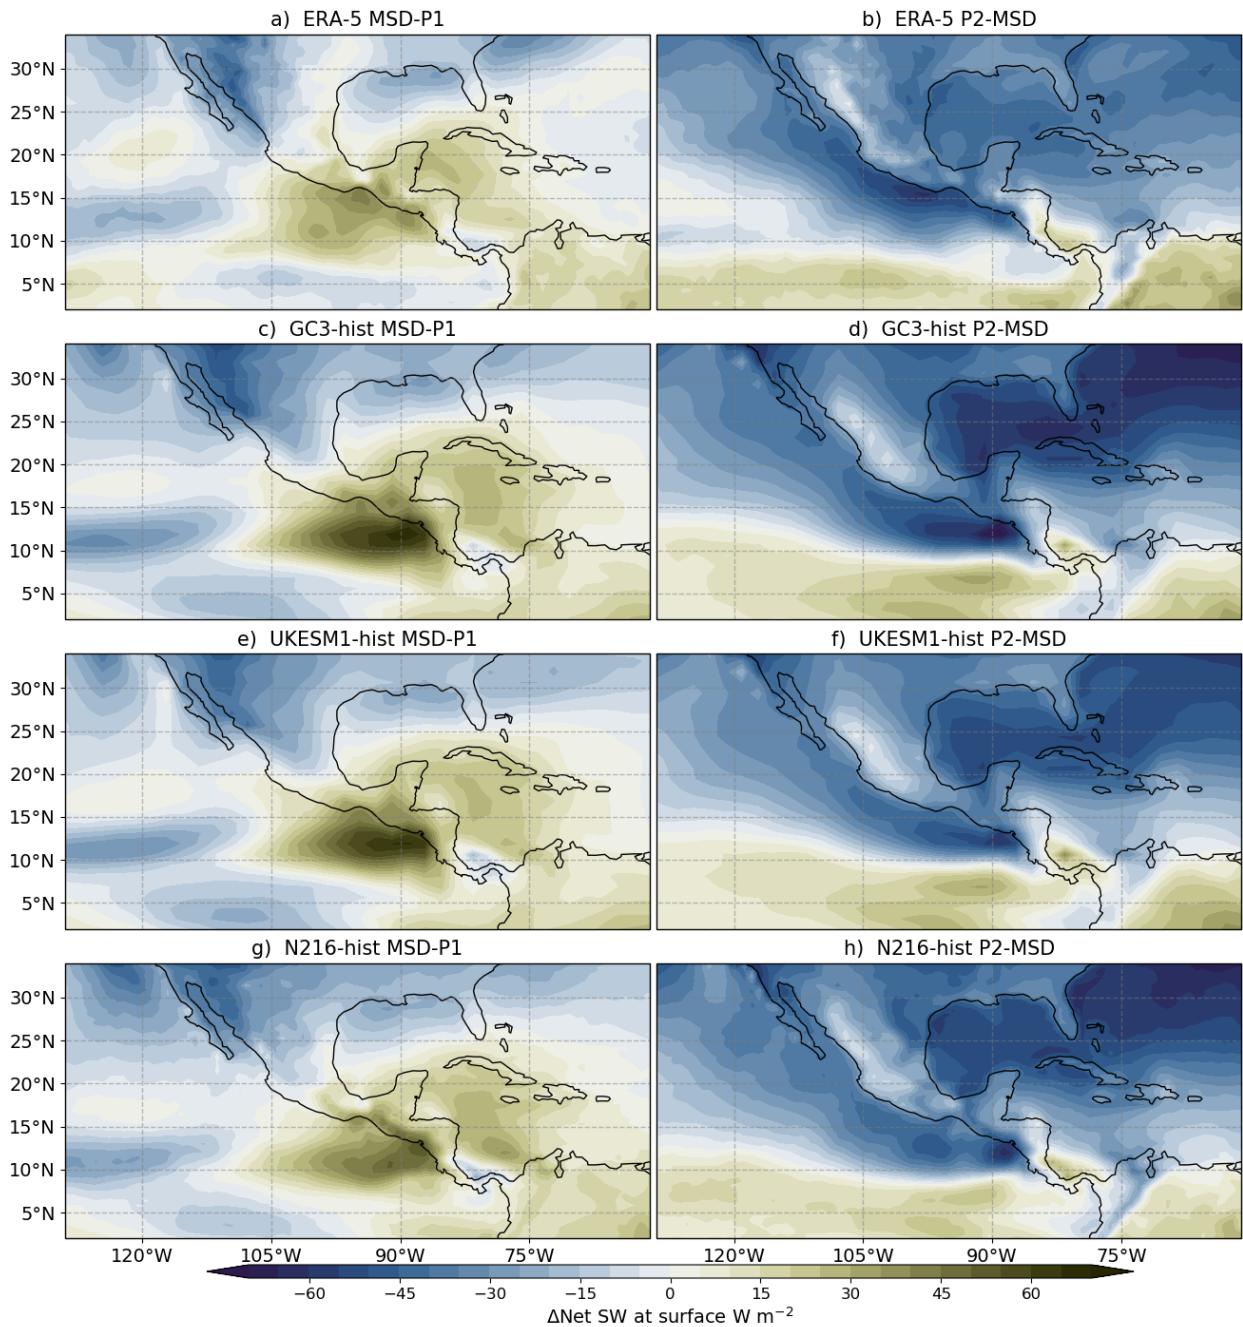

Figure 6.17: As in Fig. 6.8, but for the net shortwave radiation [W m^{-2}] at the surface.

SW energy absorption at the surface, of about 30 W m^{-2} in ERA5 and 40 W m^{-2} in the simulations. In contrast, for the P2-MSD differences, a notable reduction in net SW energy is observed throughout the North American continent but the maximum reduction is found on the western coast of southern Mexico. One might reasonably then suspect that the increased SW absorption during the MSD may indeed be the cause or part of the mechanism for the

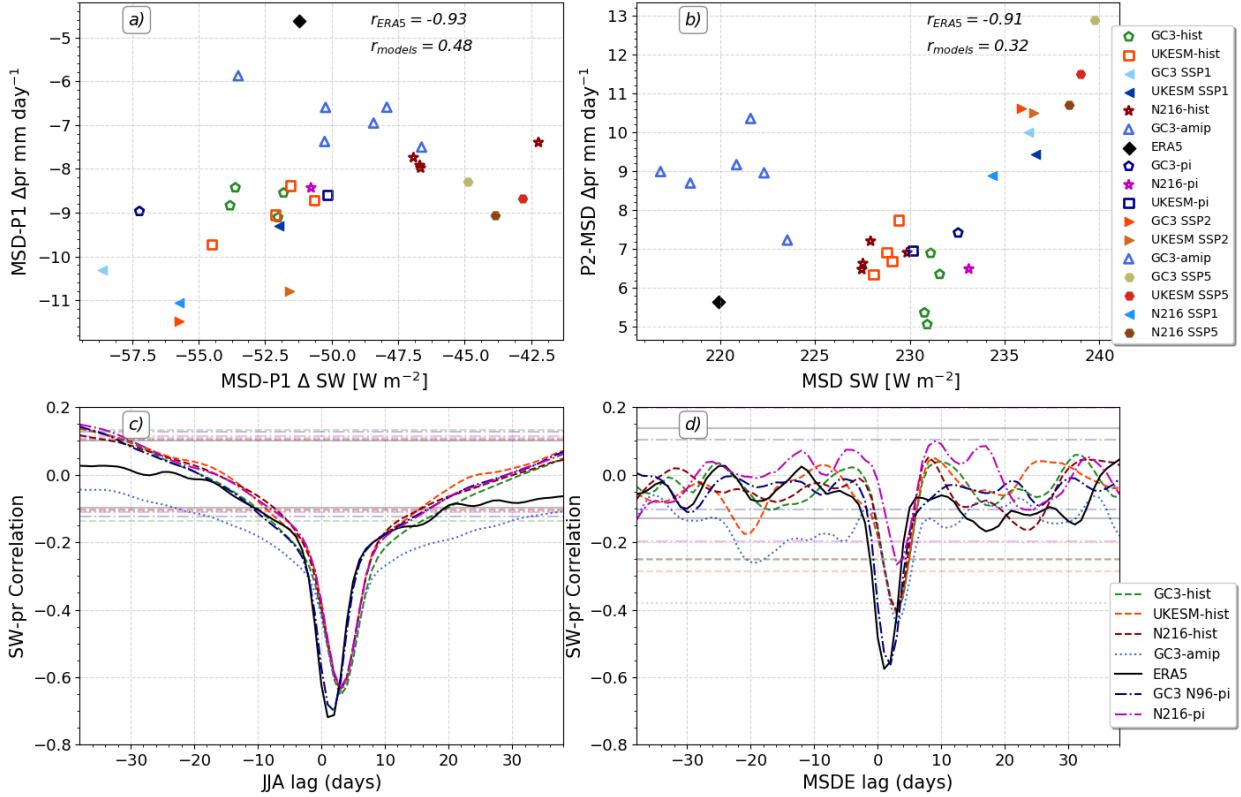

Figure 6.18: (a, b) Scatter of the mean changes to the net short-wave (SW) at the surface (abscissa) with respect to changes in precipitation for different MSD stages. (c, d) Lagged-regression coefficients between the net shortwave absorption in the East Pacific and precipitation over the MSD region for the (c) the JJA season and (d) around the MSDE date.

second peak of precipitation, as suggested by both Magaña et al. (1999) and Karnauskas et al. (2013). However, this could just be a correlation that highlights the coupling between clouds, radiation and precipitation and not necessarily that SW heating is the driving mechanism.

These hypotheses are further tested through scatter and lag-lead regression analysis (Figure 6.18). The changes to the net SW at the surface are unrelated to the interannual variability of precipitation in ERA5. The reduction in SW in the MSD-P1 periods shows a null correlation with the changes of precipitation during the same stages, whereas the net SW absorbed in the EP during the MSD period is negatively correlated with precipitation during the second peak. In other words, years where less shortwave is absorbed in the EP are years stronger second peaks in the MSD region, in contrast to previous hypotheses.

Furthermore, in the MOHC CMIP6 experiments there appears to be only a modest relationship between net SW and precipitation. The changes to SW during the MSD-P1 are

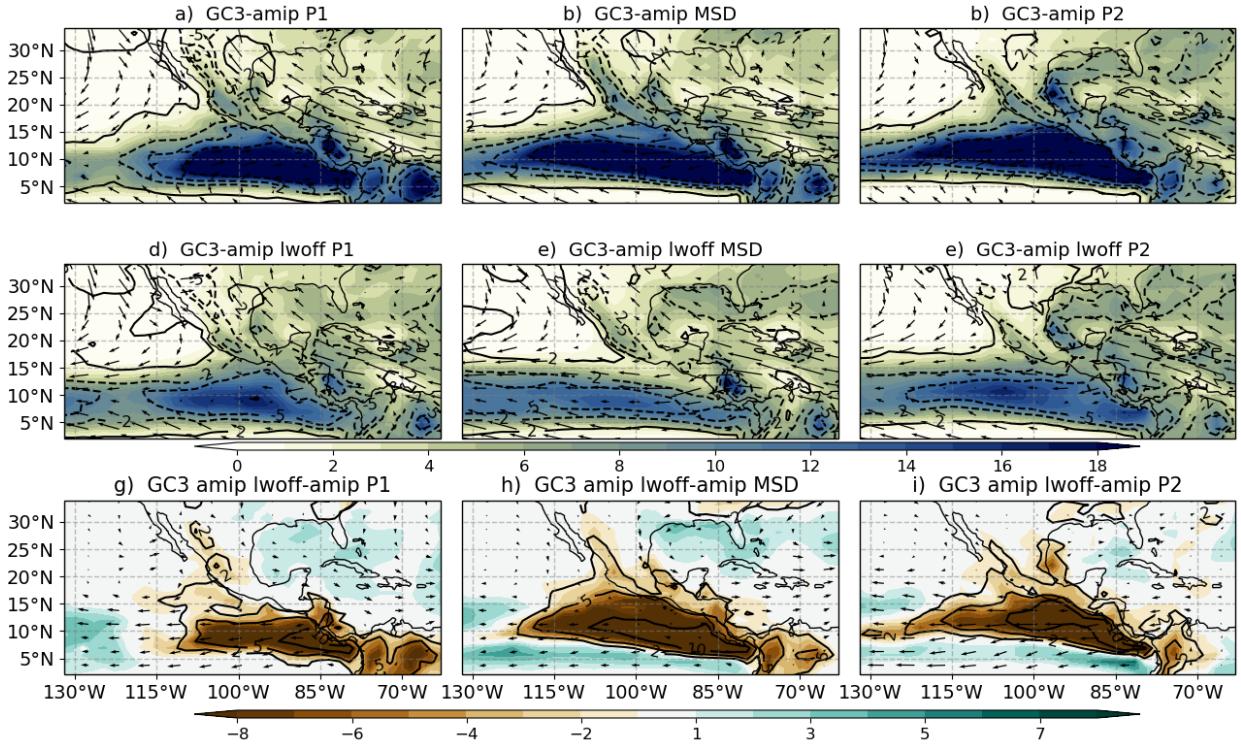

Figure 6.19: Composite mean precipitation (shading in mm day^{-1}), vertical velocity (contours in $10^{-2} \text{ Pa s}^{-1}$) and 850 hPa wind speed (vectors) for the P1, MSD and P2 periods in the (a-c) GC3-amip and (d-f) GC3-amip lwoff experiment. (g-i) shows the difference between the lwoff-amip and the amip experiments.

only modestly related to precipitation as simulations that have the smallest changes to net SW in this period do not exhibit the smallest changes to precipitation. Similarly, a very weak relationship between SW and precipitation is found within the different experiments to relate the net SW at the surface during the MSD and the strength of the second peak.

Lag-lead relationships (Figure 6.18c, d) confirm that there is a strong negative correlation between SW and precipitation at lag 0. This negative correlation illustrates that strong precipitation periods are associated with less shortwave absorbed by the surface, due to the high clouds blocking incoming SW. Correlations are not significant outside of lag -5 to 5 days near the MSDE date, although they appear significant for some coupled simulations at lags of -40 days when the entire JJA season is considered. These results are contradictory with the argument of Karnauskas et al. (2013) who argued a lagged relationship between shortwave absorption at the surface and precipitation at the end of the MSD.

Finally, while the incoming SW radiation plays an important role in several theories for

the MSD, the LW effects have important consequences in monsoon dynamics (Guo et al., 2015; Byrne and Zanna, 2020). The GC3-amip lwoff experiment is part of the contributions from the Cloud Feedback MIP (CFMIP) (Webb et al., 2017) to CMIP6. This experiment is identical to the GC3-amip experiment except that the treatment of the LW in the radiation code in the model is not affected by the presence of clouds. The radiation code does not assume all LW fluxes to be under clear-sky conditions. In other words LW heating is independent from clouds, so decoupling radiative and cloud processes.

The impact of the LW CRE for precipitation in the Mesomerican region is critical (Figure 6.19). When the LW CREs of clouds are ignored, precipitation over the whole domain is greatly reduced (50-80%), ascent becomes weaker and the low-level circulation also weakens. These results are in agreement with previous studies (Guo et al., 2015; Byrne and Zanna, 2020) that show that cloud radiative heating strengthens the local and regional circulation in a monsoon. The circulation and precipitation is so diminished in GC3 amip-lwoff that this is the driest simulation found in this chapter (Figure 6.7) and the variations between the MSD and the two peak periods of precipitation are almost undistinguishable.

This section diagnoses the seasonal cycle and spatial variability of CRE at the surface as depicted by ERA5 and the CMIP6 simulations. The net CRE at the surface is dominated by the SW term, indicating the strong effect that convective clouds have to block SW radiation from reaching the surface throughout the rainy season. The total absorbed SW shows a double-peak structure, with the second peak appearing at the end of the MSD period for both ERA5 and CMIP6 simulations, as suggested in the solar declination angle hypothesis Karnauskas et al. (2013). However, the strength and timing of the changes to the SW absorption suggest that the relationship between SW heating and precipitation is more of a correlation than a causal link from the SW to the precipitation.

6.6 The role of the Caribbean Low-Level Jet

The previous sections evaluate the SST radiative-convective feedback and the solar declination angle hypotheses whereas this section examines the role of the Caribbean Low-Level Jet (CLLJ) for the MSD of Mesoamerica. Section 6.3 shows that the seasonal cycle of the

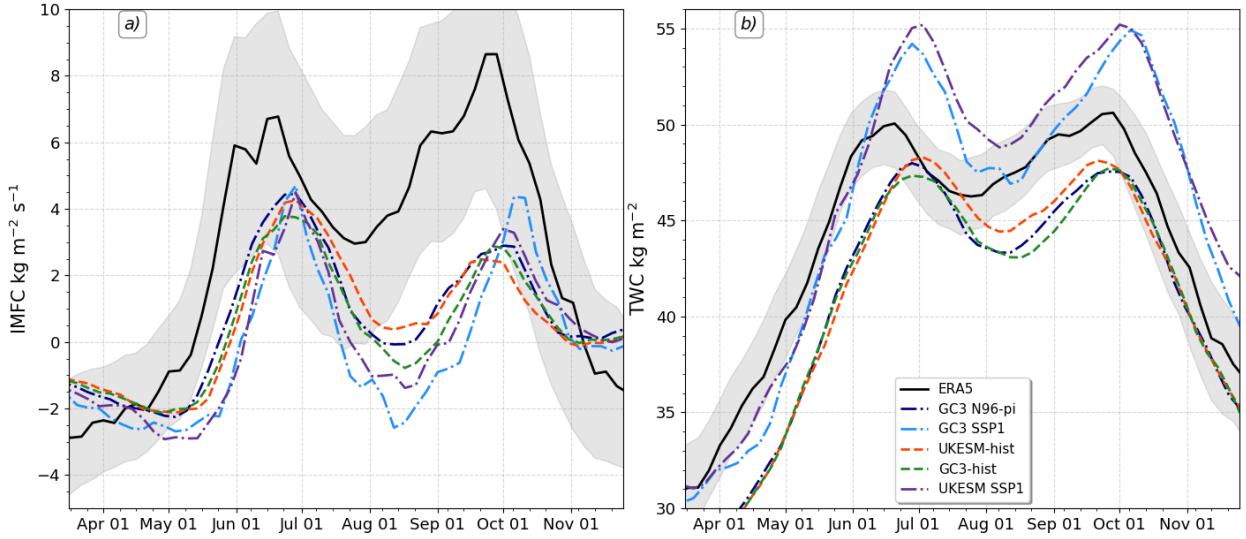

Figure 6.20: Seasonal cycle of (a) IMFC and (b) TWC averaged over the MSD region.

CLLJ, is well represented by the simulations (see Figure 6.9d), but the timing of the peak magnitude of the CLLJ in the models is delayed by about three weeks with respect to ERA5. The timing of the start of the MSD is notably also delayed in the models by around 10 days, according to Table 5.3 in the previous chapter. This evidence is suggestive that the CLLJ may be playing a role in the timings of the MSD in the simulations, which would be consistent with previous hypotheses (e.g. Herrera et al., 2015; Martinez et al., 2019).

The main dynamical argument that links the MSD in southern Mexico and Central America and the CLLJ is centred around variations in the moisture flux convergence (MFC), and subsequently in the total water content (TWC) (see e.g. Gamble et al., 2008; Herrera et al., 2015; Martinez et al., 2019; Zermeño-Díaz, 2019). For this reason, this section examines the CLLJ magnitude as measured by the 850 hPa zonal wind in the Caribbean Sea (see box in Figure 6.4), and the integrated moisture flux convergence (IMFC) and TWC in the MSD region. The IMFC was calculated using the following equation from daily ERA5 data and daily data from the simulations:

$$IMFC = -\left\langle \nabla \cdot \vec{u}q \right\rangle, \quad (6.3)$$

where q is the specific humidity at each pressure level, \vec{u} is the wind vector and ∇ is the horizontal divergence operator and the $\langle \rangle$ operator denotes column integrals in the troposphere.

The seasonal cycle of the IMFC and TWC (Figure 6.20) averaged over the region of the MSD shows a strong bimodal signal, with two maxima in IMFC and TWC occurring roughly at the same time as the two peaks in precipitation and a minimum found during Midsummer. The simulations follow closely the variations of the seasonal cycle of ERA5, but with a weaker IMFC over the region in all the simulations, particularly after the period of the first peak of precipitation.

The magnitude of the two peaks of IMFC is fairly similar for all the simulations, in contrast with the asymmetry between the first and second peaks of precipitation, e.g., the historical experiments show a wetter first peak than the second peak. The IMFC during MSD, in contrast, shows notable differences amongst experiments, with the SSP1 experiments showing a smaller IMFC compared to the historical and piControl experiments, in fact in early August the IMFC is negative (indicative of moisture divergence) in the SSP1 experiments.

The magnitude and timings of the two peaks in TWC is fairly similar amongst the piControl and historical experiments and ERA5, albeit some differences. The drying of the column in the simulations during midsummer occurs weeks after the drying in ERA5, which agrees with the differences in the seasonal cycle of precipitation. The low-emission scenario (SSP1) experiment show a higher TWC indicative of a moistening of the column throughout all the seasons for a relatively low greenhouse forcing compared to the historical experiments.

The IMFC, TWC and 850-hPa wind variations associated with the MSD (MSD-P1 and P2-MSD) are shown in Figure 6.21 for ERA5 and two simulations. The patterns observed in the low-level wind vectors associated with the MSD timings follow closely the previously reported "MSD patterns" described by Zermeño-Díaz (2019); Zhao et al. (2020), which confirms that the WT method is able to extract similar patterns in the low-level wind associated with the MSD to other techniques. The wind flow pattern in the MSD-P1 panel is characterised, both in ERA5 and the simulations, by modest northeasterly anomalies in the Gulf of Mexico and the CSEA and strong easterly anomalies over the EP region. These wind anomalies indicate that as the wetter first peak period transitions to the drier MSD, the wind field changes from a weak low-level westerly wind to an easterly wind (see also Figure 6.9c). At the end of the MSD, the wind direction changes again to a westerly direction in the East

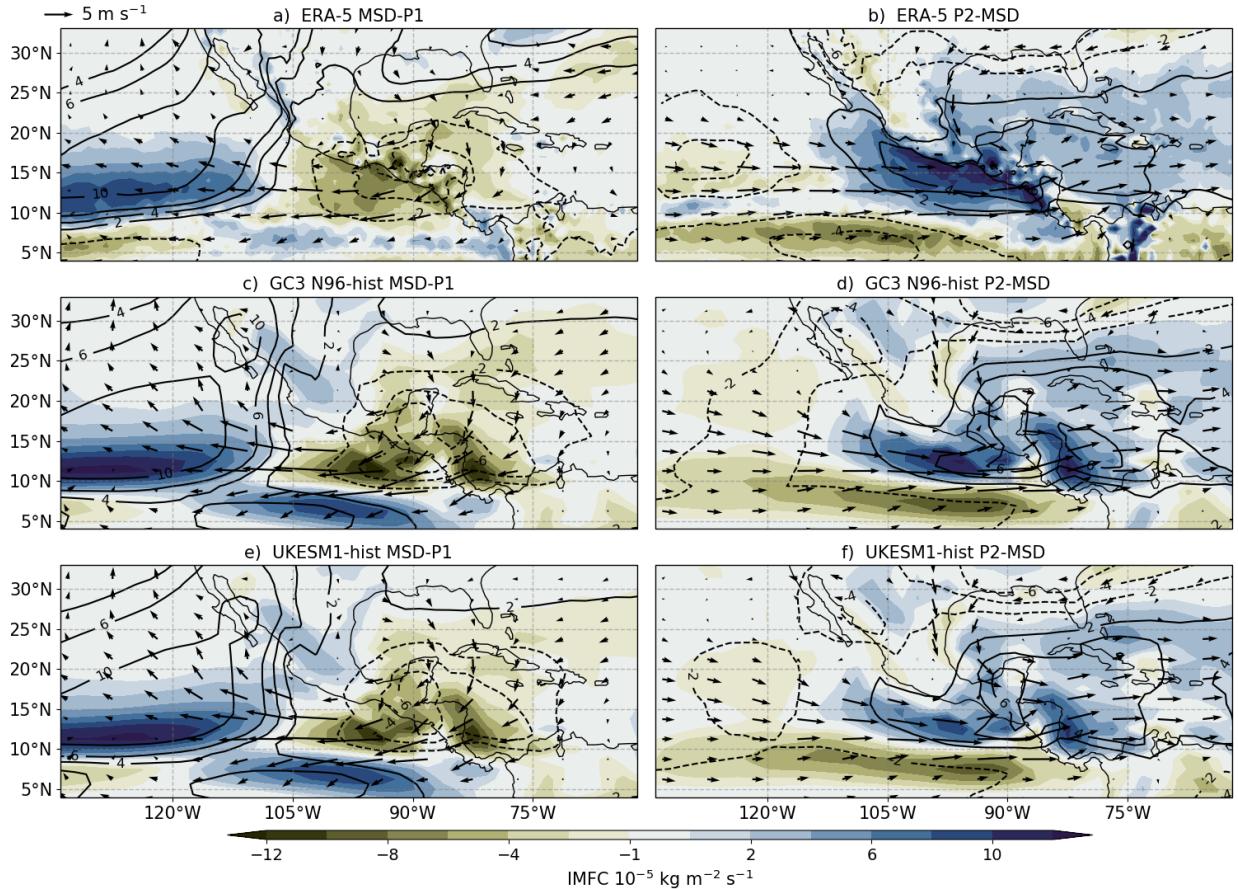

Figure 6.21: As in Figure 6.10, but showing variations in the IMFC (shading), TWC (contours in units of kg m^{-2}) and 850-hPa wind (vectors).

Pacific, whereas the wind anomalies in the CSEA turn to westerlies indicative of a weakening of the CLLJ, coincident with the second peak of precipitation observed in the MSD region.

The IMFC and TWC show coherent variations with the timings of the seasonal cycle of precipitation in the MSD region, with less moisture convergence and precipitable water in the column during the drier period compared to the two peak periods. In contrast, west of the coast at around the 125°W , during the MSD there is increased TWC and IMFC in ERA5 and in the simulations, in agreement with the previous sections which showed increased convective activity in this region. Simultaneous to the drying of southern Mexico and Central America during the MSD, the North American monsoon region moistens (increased TWC and IMFC).

The IMFC and TWC anomalies associated with the end of the MSD period, depicted by the P2-MSD panel, show positive differences in the MSD region and negative anomalies

southward, suggesting increased IMFC and TWC over southern Mexico and northern Central America, in agreement with the secondary increase in precipitation. Positive TWC and IMFC differences extend from the MSD region to the east into Cuba, the Caribbean Sea and the Gulf of Mexico. This moistening coincides with increased moisture divergence to the south of the MSD region in the East Pacific (120-90°W, 3-10°N) and decreased TWC.

A scatter plot of the mean changes to the IMFD, TWC and the CLLJ and their relationship to the synchronous variations in precipitation (Figure 6.22) confirm that these diagnostics are deeply related to the timings and strength of the seasonal cycle of precipitation. The interannual variability of the precipitation differences MSD-P1 in ERA5 are very well explained by the variability of the TWC ($r = 0.87$) and the IMFC ($r = -0.98$) but less so by the CLLJ ($r = 0.14$). The inter-experiment MSD-P1 precipitation differences can largely be explained by the differences in IMFC changes during the MSD-P1 periods ($r = 0.78$).

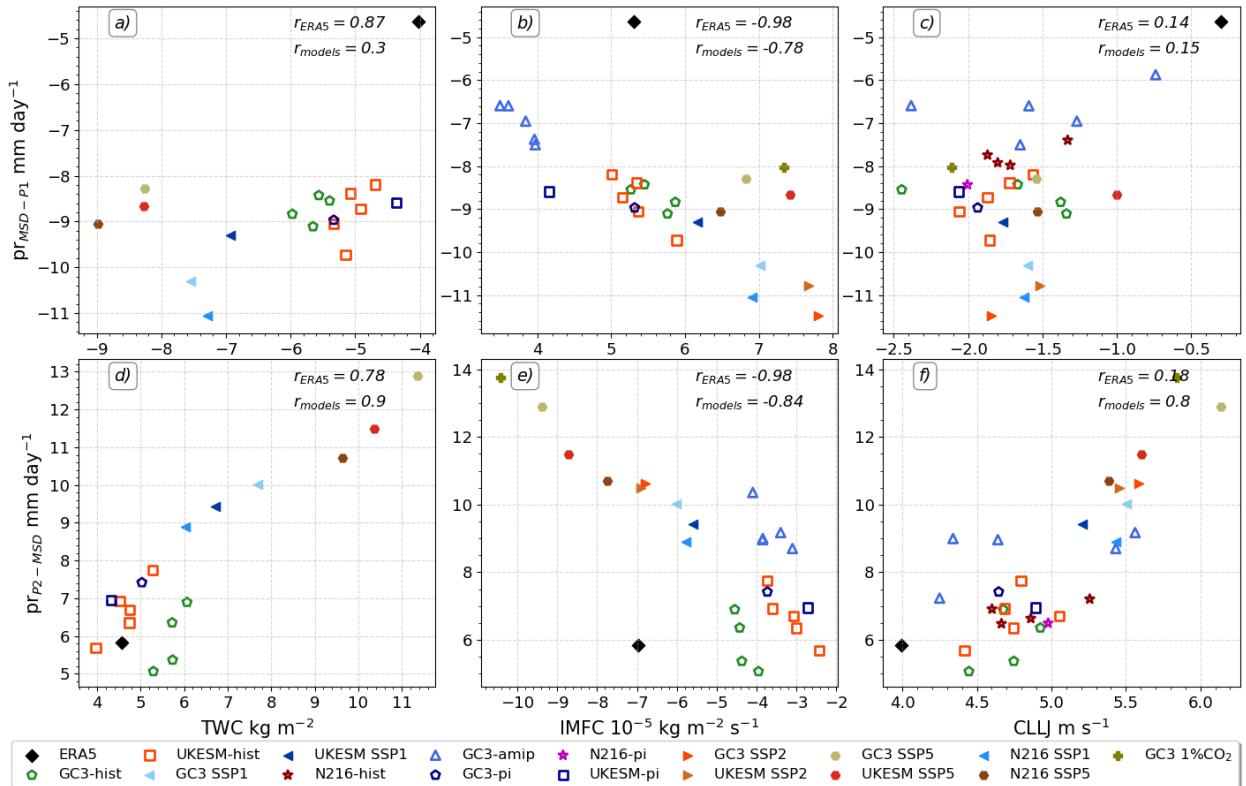

Figure 6.22: As in Figure 6.12, showing the scatter of mean changes (a-c) MSD-P1 and (d-f) P2-MSD periods, but using the (a, d) IMFD and (b, e) TWC in the MSD region and the (c, f) CLLJ on the x-axis and precipitation in the MSD region in the y-axis.

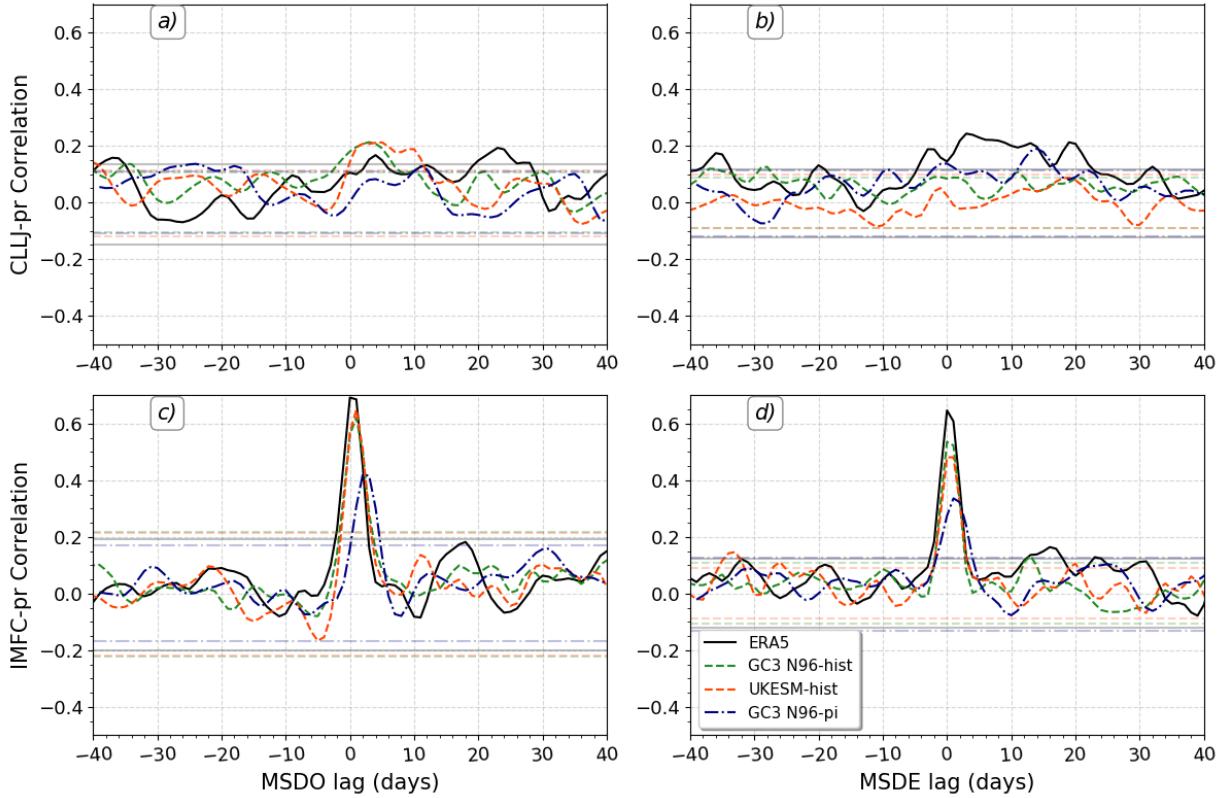

Figure 6.23: Lagged correlations between precipitation in the MSD and the (a, b) CLLJ, defined as the 925 hPa zonal wind averaged over the CSEA region, and (c, d) the IMFC over the MSD region. Correlations are shown with lags computed with respect to the (a, c) onset and (b, d) end dates.

However, the changes in the CLLJ and IMFC in the simulations can not explain the precipitation differences between the runs in the MSD-P1 periods.

The changes from the MSD to the second peak of precipitation (Fig. 6.22) in the simulations are very well explained by the mean variations to the CLLJ, the TWC and the IMFC. However, for the interannual variability of ERA5, only changes to the TWC and IMFC show significant and relatively high correlations. These results would suggest that variability in the CLLJ can explain several differences in the magnitude of the P2-MSD differences in the models, possibly through the modulation of the CLLJ on the TWC and the IMFD over the continent; nevertheless, the observed interannual variability of the CLLJ cannot explain the interannual variability in the strength of the second peak.

The synchronous relationship found in the previous scatterplot is further tested via lagged correlations (Figure 6.23). These correlations do not show any evidence of robust

relationship between the CLLJ or the IMFC with precipitation at any lags. In particular, the correlations of precipitation with the CLLJ are not higher than 0.3 at any lag and only become significant for a few days in some simulations. In particular, around the MSDE date, no correlation at negative lags is significant and positive which is at odds with the hypothesis that CLLJ is responsible for the end of the MSD.

However, the strength of the CLLJ may not be the relevant factor, but rather the influence of the CLLJ on the IMFC. The correlation of IMFC with precipitation shows a strong positive correlation, both at MSDO and MSDE in reanalysis and models around lag 0, and similar results are found for TWC-pr correlations (not shown). However, there is little evidence that this relationship is of a lagged nature, as the correlations are not significant away from the 0 lag.

6.7 A short look at the MSD through the lense of the moist static energy budget

The results in the previous sections suggest that only some elements of the CLLJ hypothesis can explain the interannual variability in the strength of the MSD in reanalysis and the differences in the CMIP6 experiments. To further explore the processes that control the start of the MSD, the moist static energy (MSE) budget is used in this section to disentangle how the column MSE budget terms vary over the wet season. The MSE budget terms are obtained, as described in section 3.3, from daily-mean values at all available levels within the troposphere for reanalysis and climate model output. Note that the radiative heating terms are not available from the CMIP archive on daily scales.

The seasonal cycle of the budget terms, as well as the boundary layer or near-surface MSE (h_b), is shown in Figure 6.24 with some quantities shown for the EP region and others for the MSD region. The vertical advection of dry (s) and moist (h) static energy show a bimodal seasonal cycle, with two peaks at the start and end of the summer season, separated by a local minimum that occurs at the end of July or early August. The simulated vertical advection of MSE corresponds well with ERA5 during boreal summer for all the simulations, although the vertical advection of s is smaller in the historical and SSP1 experiments

during the MSD and second peak periods. The vertical advection of s is higher in the GC3 amip experiment during late summer compared to other experiments, which is important because this simulation has the wettest second peak.

The sum of the latent and sensible heat fluxes in the EP region show a clear bimodal signal in the experiments but not in ERA5. The experiments also show very large positive biases in surface fluxes during both periods of peak precipitation, especially the GC3 amip experiment. These biases in the surface fluxes in the EP are possibly one of the reasons for the very wet bias found in the EP ITCZ in these models.

The theory by Karnauskas et al. (2013) suggests that the net shortwave surface energy

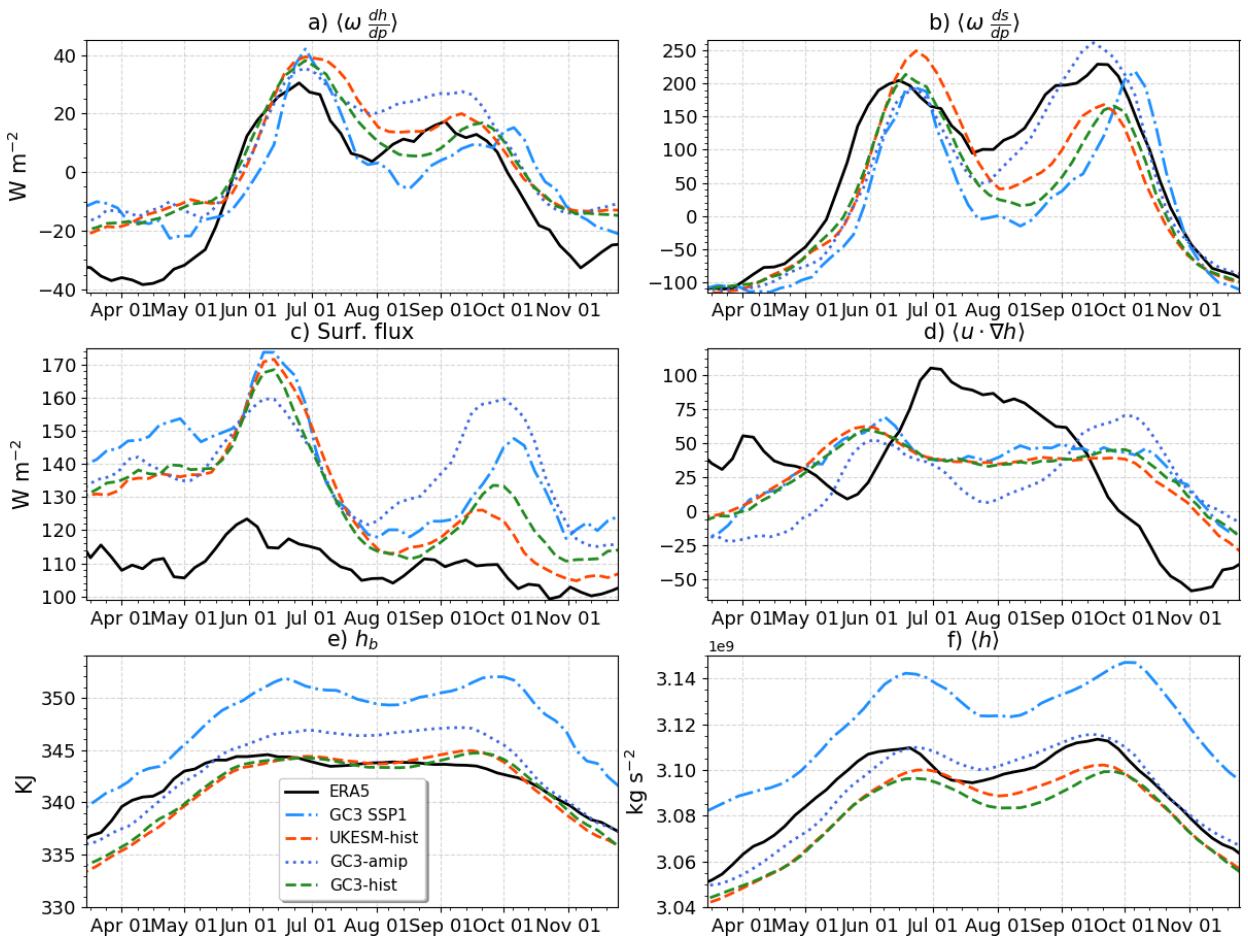

Figure 6.24: Pentad-mean seasonal cycle of the moist static energy budget terms. Vertical advection of (a) moist and (b) dry static energy, (c) the sum of the latent and sensible heat fluxes, (d) horizontal advection of MSE, (e) boundary layer MSE (h_b) and total column MSE ($\langle h \rangle$). The quantities in panels c,d were averaged over the EP region and the rest of the panels over the MSD region.

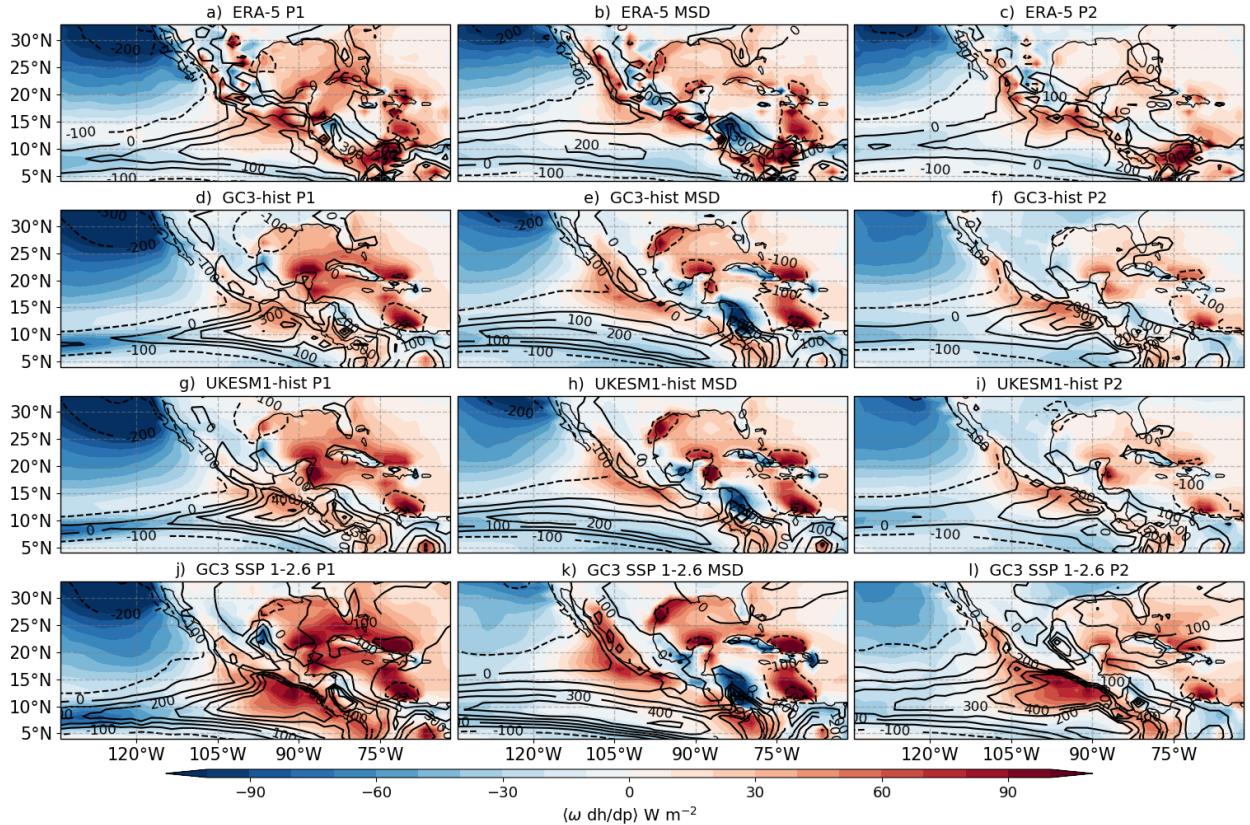

Figure 6.25: Composites of mean $\langle \omega dh/dp \rangle$ (shading in W m^{-2}) and $\langle \omega ds/dp \rangle$ (contours in W m^{-2}).

balance being strongly modulates the various stages of the MSD, through an influence on the surface or boundary layer MSE (Fig. 6.24e). However, in most of the simulations and ERA5, h_b in the MSD region follows a plateau-like seasonal cycle with a clear increase during spring, a plateau during summer and a sharp decrease in October at the end of the rainy season. The SSP1 experiment shows a decrease in h_b in August but this is fairly modest compared to the magnitude of the change in h_b at the end and start of the summer.

Similarly, the total column h shows a modest bimodal seasonality in reanalysis and simulations, i.e., $\langle h \rangle$ decreases at the midsummer. The low-emission scenario shows a notable increase in total column h compared to historical and pre-industrial experiments. In spite of this increase in total column h in SSP1, the total precipitation is not increased uniformly over all the stages of the wet season in scenario experiments (see Fig. 6.7), so changes to TWC do not explain variations to precipitation throughout the wet season in this region.

The spatial distribution of the mean $\langle \omega dh/dp \rangle$ and $\langle \omega ds/dp \rangle$ (Figure 6.25) during the

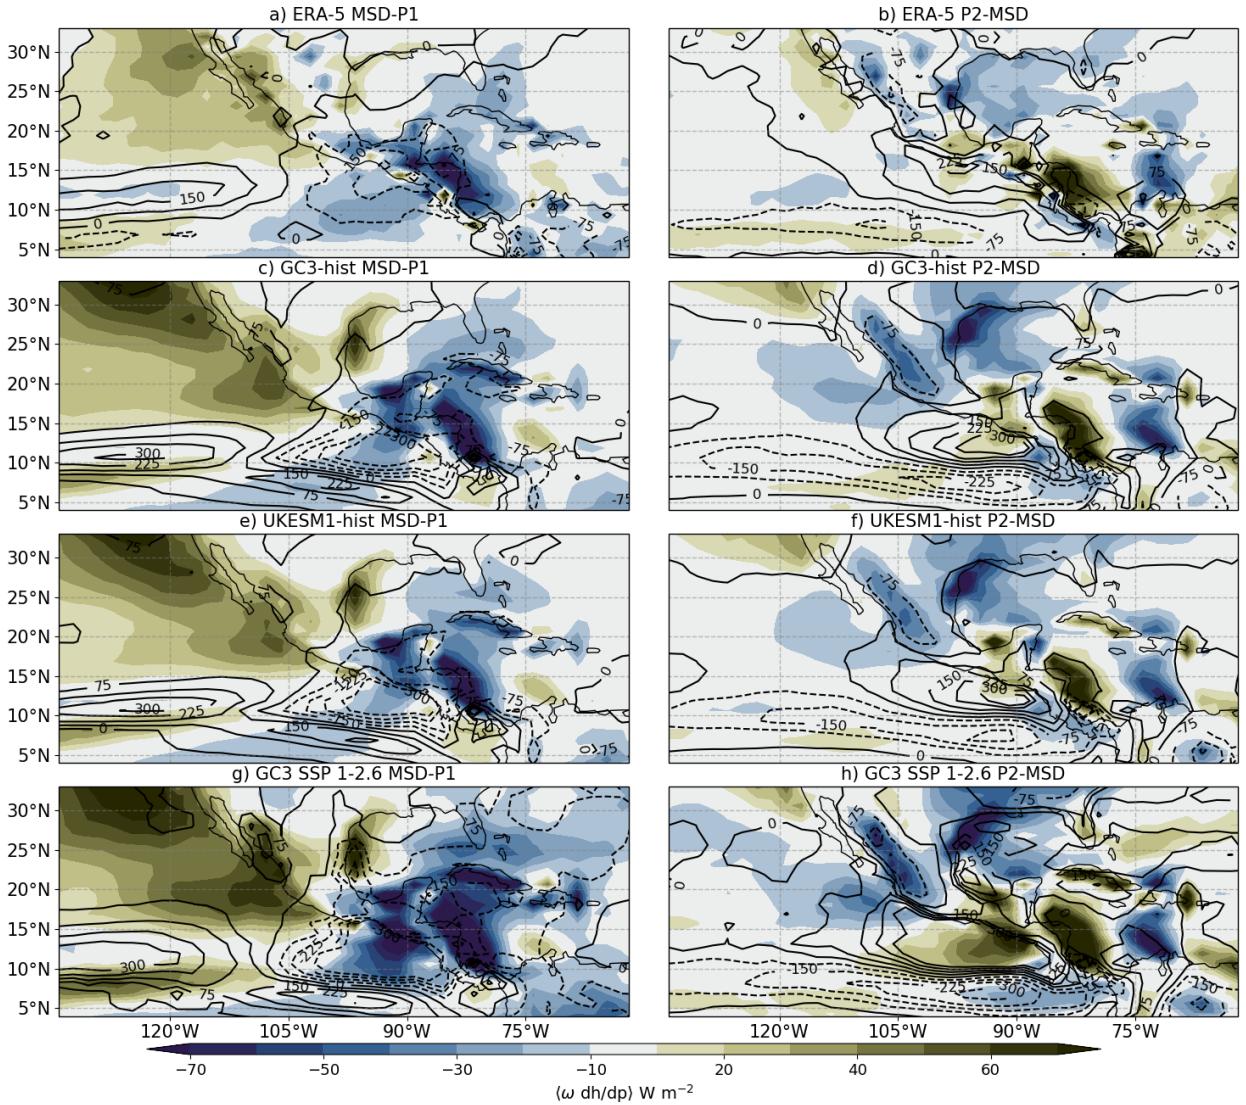

Figure 6.26: Composites of the differences (a, c, e, g) MSD-P1 and (b, d, f, h) P2-MSD of $\langle \omega dh/dp \rangle$ (shading in $W m^{-2}$) and $\langle \omega ds/dp \rangle$ (contours in $W m^{-2}$).

three stages of the MSD seasonal cycle show a good agreement between the experiments and reanalysis. The highest values of $\langle \omega ds/dp \rangle$ are found on the western coast of northern Central America, in the easternmost position of the ITCZ. Positive values of $\langle \omega dh/dp \rangle$ are found in the Caribbean Sea, the Gulf of Mexico and over the MSD region throughout the three stages of the MSD. Negative values of $\langle \omega dh/dp \rangle$ and $\langle \omega ds/dp \rangle$ are found over the coast of California throughout the wet season.

The changes to the $\langle \omega dh/dp \rangle$ and $\langle \omega ds/dp \rangle$ during the MSD periods (Figure 6.26) show that in the MSD region, $\langle \omega dh/dp \rangle$ and $\langle \omega ds/dp \rangle$ are reduced during the MSD period

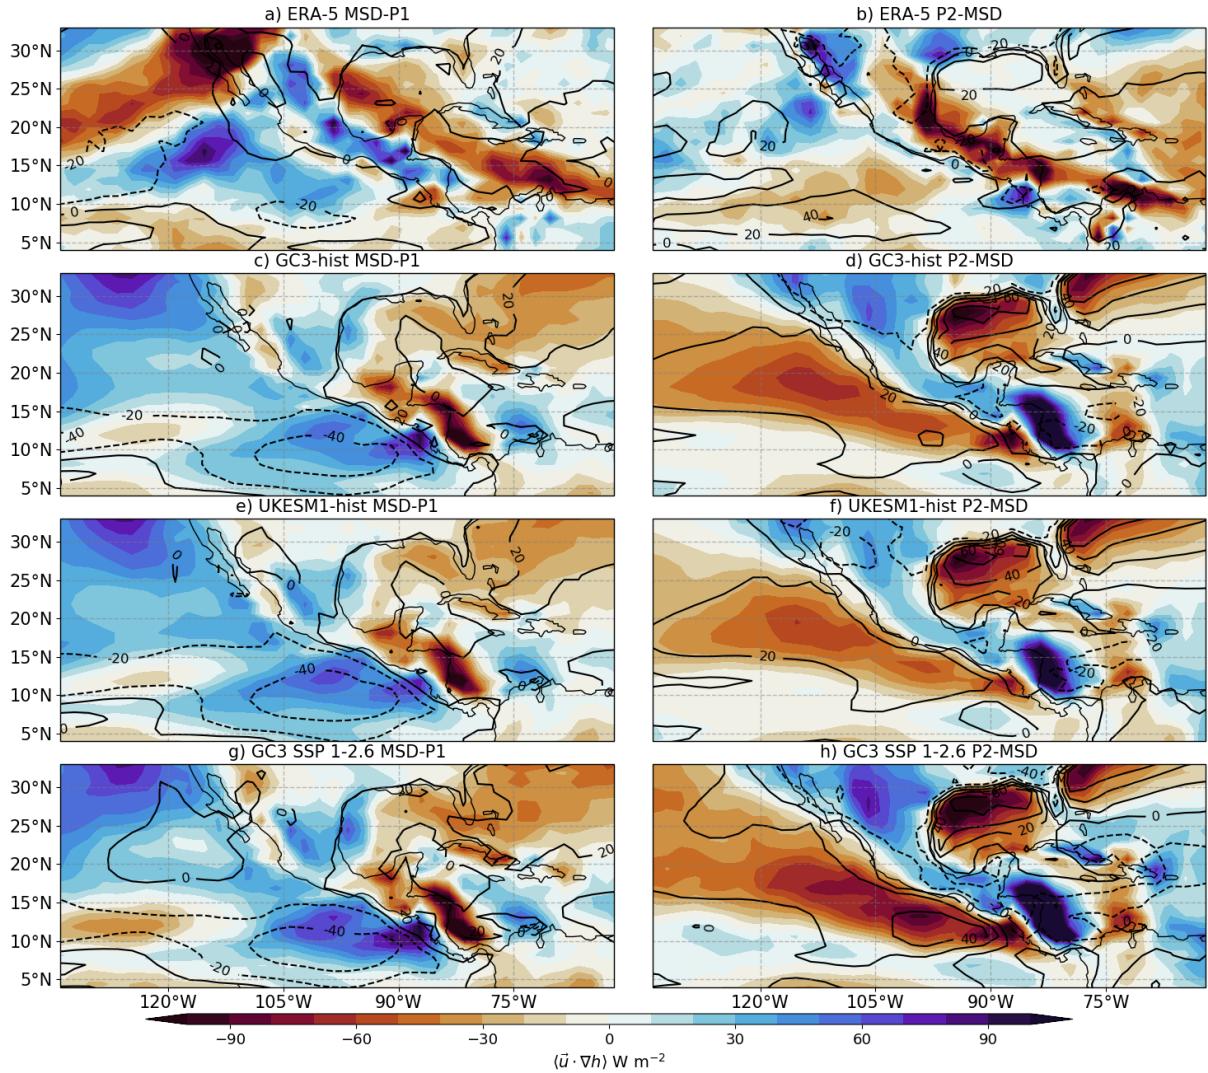

Figure 6.27: Composites of the differences (a, c, e, g) MSD-P1 and (b, d, f, h) P2-MSD of $\langle \vec{u} \cdot \nabla h \rangle$ (shading in W m^{-2}) and total surface fluxes (F) (contours in W m^{-2}).

compared to the P1 period, this difference is maximized right at the exit of the Gulf of Tehuantepec, in southwestern Mexico. Simultaneously, from the P1 to the MSD period, $\langle \omega_{ds}/dp \rangle$ increases west of the MSD region near the 125°W region whereas $\langle \omega_{dh}/dp \rangle$ increases in northern Mexico and in the Gulf of California.

At the end of the MSD (Figure 6.26), $\langle \omega_{dh}/dp \rangle$ and $\langle \omega_{ds}/dp \rangle$ increase in the MSD region. Again, the maximum difference of $\langle \omega_{ds}/dp \rangle$ is found in the Gulf of Tehuantepec region. The North American monsoon region shows a decrease in both $\langle \omega_{dh}/dp \rangle$ and $\langle \omega_{ds}/dp \rangle$. Both for the P2-MSD and MSD-P1 panels, the experiments are able to reproduce the spatial patterns of these changes to these budget terms. Furthermore, the SSP1 experiment shows

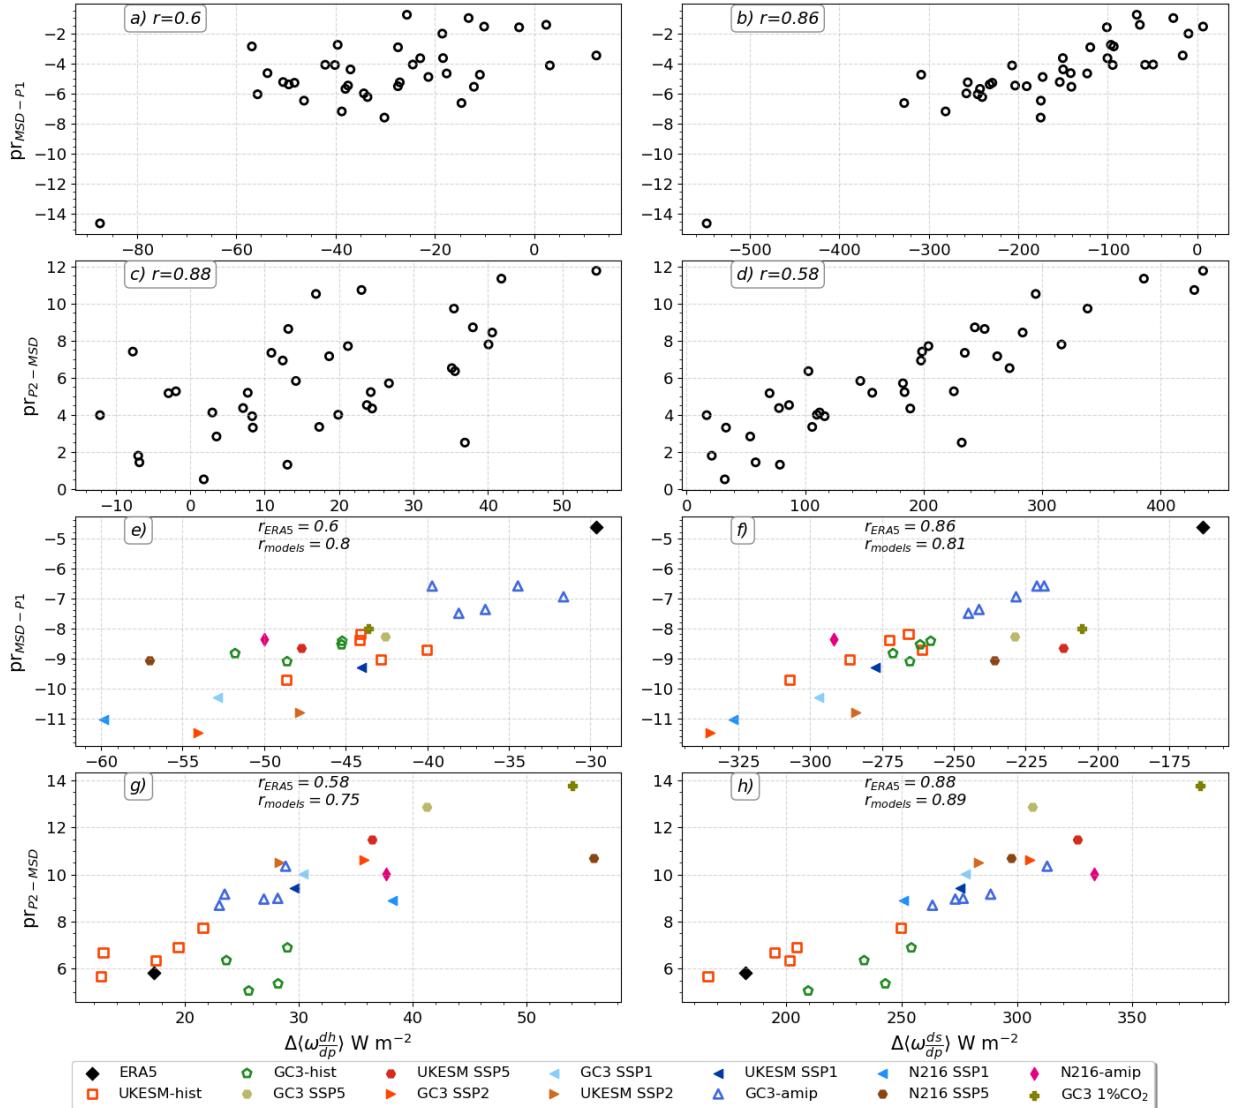

Figure 6.28: Scatterplot of the relationship between the area-averaged mean vertical advection of dry and moist static energy and precipitation over the MSD region. (left) Differences in $\langle \omega dh/dp \rangle$ and (right) in $\langle \omega ds/dp \rangle$ on the x-axis with corresponding differences in precipitation on the y-axis computed for differences amongst MSD-P1 and P2-MSD periods, as indicated on the y-axis label. (a-d) Interannual variability of ERA5 where each dot represents one year in ERA5. In (e-h) the differences represent the mean values for all years in each dataset.

larger differences between the MSD stages compared to the historical experiments.

The horizontal advection term and the surface fluxes also show notable differences associated with the MSD timings (Figure 6.27). In the MSD-P1 period, decreased surface fluxes in the easternmost Pacific Ocean are observed in the three simulations and, to a lesser degree, in ERA5. These differences suggest that in the models, surface fluxes decrease

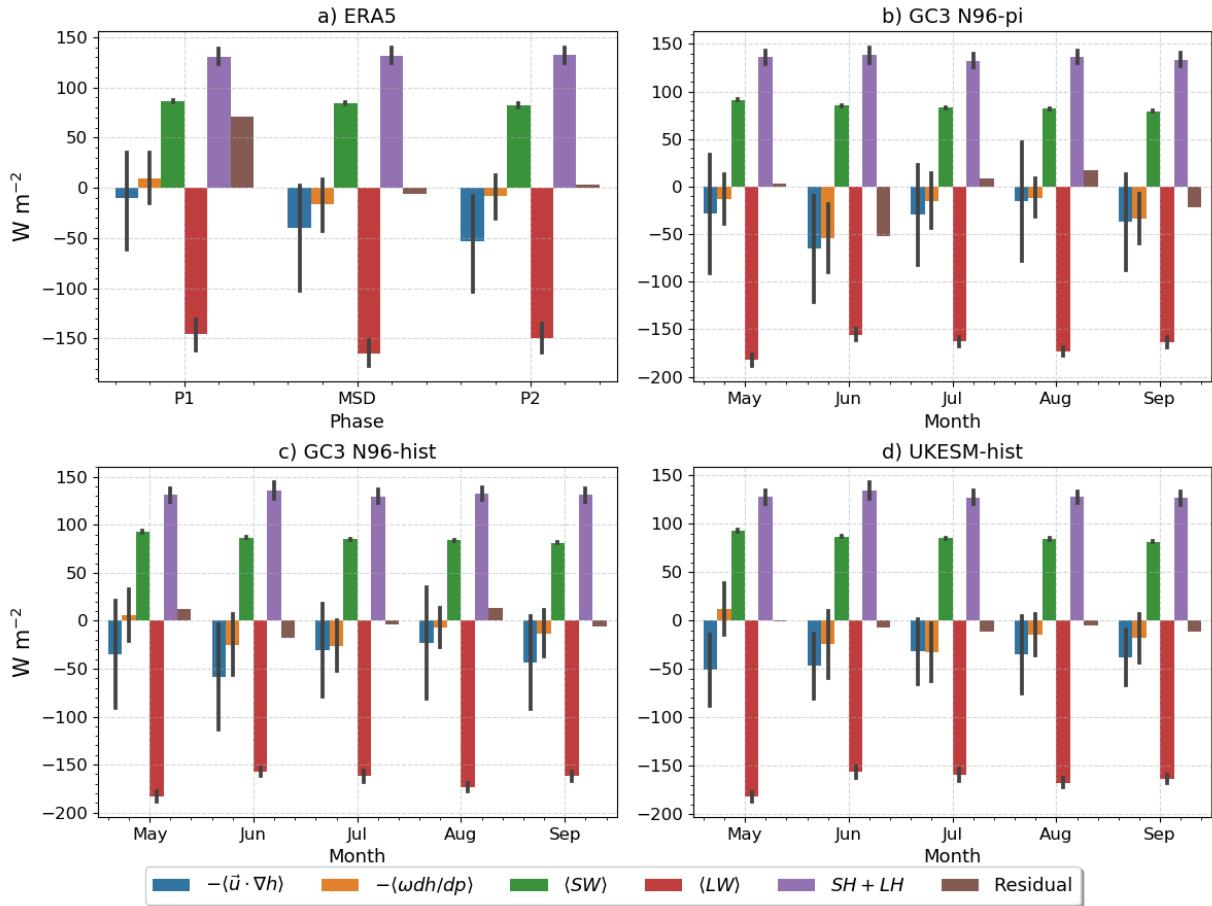

Figure 6.29: Barplots of the area and time-averaged MSE budget terms: horizontal advection ($\langle \vec{u} \cdot \nabla h \rangle$) and vertical advection ($\langle \omega dh/dp \rangle$), longwave ($\langle LW \rangle$) and shortwave ($\langle SW \rangle$) heating and the sum of sensible (SH) and latent heat (LH) fluxes. The residual or addition of all the terms is also shown in each panel. (a) Budget terms computed from ERA5 in the MSD region in the P1, MSD and P2 periods and (b-d) show the monthly-mean values of the budget terms from three CMIP6 simulations. [The error bars indicate the standard deviation for each month/phase.](#)

as precipitation decreases from the wet first peak period to the dry MSD period. In the simulations, these negative surface flux anomalies are collocated with negative differences of the horizontal advection of MSE term. The opposite patterns appear for both $\langle \vec{u} \cdot \nabla h \rangle$ and surface fluxes in the P2-MSD differences.

The scatter of the relationship between precipitation and the vertical advection of dry and moist static energy during the wet season (Figure 6.28) indicates that the vertical advection term is strongly linked to precipitation variations, both in ERA5 as in the simulations. Figure 6.28 shows that the interannual variability of vertical advection of dry and moist static energy in ERA5 is strongly related to interannual variations in the precipitation changes during the

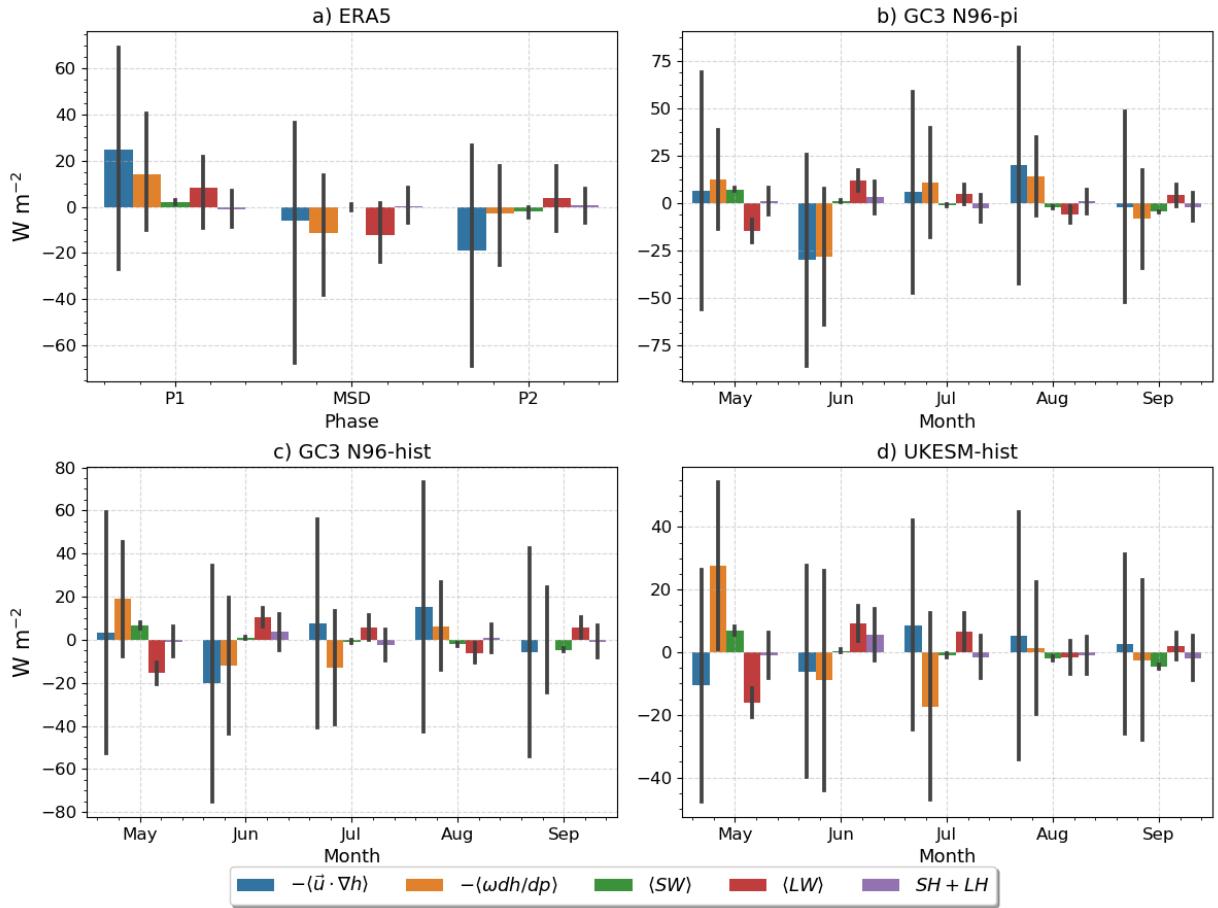

Figure 6.30: As in Figure 6.29 but each term is shown as anomalies from the wet season (JJAS) mean.

MSD. Negative differences of $\langle wdh/dp \rangle$ and $\langle wds/dp \rangle$ are observed in MSD-P1 panel whereas increases of these terms occur from the MSD period to the second peak period in ERA5 and in the experiments. Specifically, $\langle wds/dp \rangle$ is the term that best explains interannual variability of the strength of the MSD, measured by the difference MSD-P1 in ERA5.

A key question then is how the MSE budget equation is balanced in the different stages of the seasonal cycle, i.e., which terms balance the changes to the vertical advection of MSE and how this balance changes from the early and late wet periods compared to the MSD period. Figure 6.29 shows the mean values of each budget term in the MSD region in ERA5 and the simulations. The results in the simulations are shown as monthly-mean values because the radiative heating data from the CMIP6 archive was only available for monthly-mean frequencies.

In ERA5 (Fig. 6.29a), the positive contributions of MSE from the shortwave heating and the surface fluxes are balanced mostly by the negative contribution from the longwave heating (radiative cooling of the column) and to second order by the horizontal and vertical advection terms. The differences in the budget terms between the P1, MSD and P2 periods (Fig. 6.30) are most pronounced for the vertical and horizontal advection terms, and the LW heating term. The horizontal advection term increases absolute magnitude (more negative contribution) and the vertical advection term changes sign (from positive to negative) during the MSD compared to the first peak period. However, from P1 to the MSD stage, the longwave radiative heating notably decreases and increases again from the MSD to P2 periods whereas the shortwave heating term appears to change very little between the stages of the rainy season.

In the CMIP6 simulations (Fig. 6.29b-d), a similar balance is observed with the largest contributions arising from the radiative heating and surface flux terms. From May to September some seasonal variations in each term are observed (Fig. 6.30b-d), for example, stronger longwave cooling in May than in June-July. The vertical advection term becomes negative during the early rainy season (June-July). As in ERA, the absolute contribution from the vertical advection term increases during the MSD with minima found in June or July in all the simulations. The contribution from the horizontal advection term increases during the months of the two peak of precipitation (May and September) and decreases during the MSD.

The MSE budget analysis is able to show what terms vary more coherently with the timing of the MSD, as well as what terms explain better the variability of the strength of the MSD. First, this section shows that vertical advection terms show a bimodal seasonal cycle, which points to the strong relationship between ω and precipitation. However, the surface h remains relatively constant throughout the rainy season, in contrast to the suggestions by Karnauskas et al. (2013). The patterns of anomalous vertical and horizontal transport of h also show strong variations synchronous to the MSD stages, suggesting that precipitation follows closely variations in h .

The comparison of individual terms shows that the variability of the horizontal advection and longwave heating terms within the rainy season is stronger than for the shortwave heating and surface fluxes (Fig. 6.30). This evidence (Fig. 6.30) suggests that LW heating

and CRE, and moisture transport may be more important than the variations in surface fluxes or the shortwave heating because their variations are more strongly linked to the MSD variations of precipitation. The horizontal advection fluctuations partially support the mechanism that links the moisture transport from the CLLJ to the precipitation in the MSD, however, further work is needed to link the CLLJ to the horizontal advection term.

6.8 Summary and discussion

The Midsummer drought (MSD) is a key element of past, present and future climates of southern Mexico, northern Central America and the Caribbean with important implications for agriculture and water management (Hellin et al., 2017; de Sousa et al., 2018; Harvey et al., 2018). However, there is no complete description of the physical mechanisms that explain the spatial and temporal variability of the MSD. This lack of understanding is magnified when investigating the MSD in global climate models used for projections of future climate, as little is known as to why only some models can reproduce the MSD (Ryu and Hayhoe, 2014).

This chapter tackled these shortcomings in the literature by investigating the processes that are linked to the MSD in CMIP6 experiments of the MOHC models, an investigation that was motivated by the two previous chapters which showed that these models reasonably reproduced the main features of the MSD signal. The first contribution of this chapter is the diagnosis of MSD timings and patterns on a sub-monthly scale, a step forward from previous studies that diagnosed the MSD on monthly-mean timescales, possibly missing key information in the process. For this purpose, the wavelet transform method (WT; Chapter 5) was used to determine the timings of the MSD on a 5-day (pentad) scale.

The WT method proved useful to separate the wet season in each dataset into three stages: the first and second peak periods (P1 and P2) and the drier period (MSD). This approach was able to reproduce the so-called MSD pattern reported in previous studies (Zermeño-Díaz, 2019; Zhao et al., 2020) using various diagnostics such as OLR, ω and the low-level wind flow. This pattern is characterised by a strong change of the zonal wind flow crossing from the Caribbean Sea into the easternmost Pacific Ocean, as well as by anomalous vertical velocities found west of the coast at around 125°W (Herrera et al., 2015; Zermeño-Díaz, 2019).

The chapter first evaluates key climate features in the region such as the seasonal cycle of the CLLJ and East Pacific SSTs. Results show that the simulations agree well with the observed seasonal cycle and that the experiments show very similar MSD patterns to ERA5. The following sections in the chapter test three hypotheses put forth to explain the MSD, which is the second key contribution from this chapter. Each hypothesis is evaluated using the WT method in two different ways. The first question was whether a hypothesis could explain the interannual variability in the strength and timing of the MSD in ERA5. The second approach focused on the CMIP6 experiments and aimed to test whether the elements of each hypothesis could explain the differences in precipitation at each stage of the seasonal cycle between the experiments.

The first mechanism proposed by Magaña et al. (1999) argues that SST-cloud-radiative feedbacks explain the MSD. In this hypothesis, the SSTs in the East Pacific should also exhibit a bimodal seasonal cycle, with a second peak in SSTs found in September. Even though Magaña and Caetano (2005) analysed this for a specific year and found no evidence of a second peak in SSTs, no study to date robustly evaluated whether observations or models confirm their hypothesis. This chapter provides evidence that in ERA5, SSTs not only do not increase at the later stages of the summer but rather decrease. While the seasonal cycle in the simulations do show a two peak structure, the composite analysis shows that as precipitation transitions from the drier MSD to the second peak periods, SSTs decrease in the Pacific coast of Central America, in contrast to the prediction of the SST-cloud feedback mechanism. No evidence is found that the variability of the East Pacific SSTs is directly associated with the precipitation over the MSD region in ERA5 or in the CMIP6 experiments.

The feedback mechanism also suggests that the second peak is a result of a second increase in downwelling shortwave radiation at the surface that results from cloud cover during the drier MSD. The solar declination angle mechanism of Karnauskas et al. (2013) also suggests that shortwave absorption has two peaks in the seasonal cycle, which leads to the two precipitation peaks. The shortwave absorption at the surface does show a bimodal seasonal cycle in ERA5 and in the simulations, as predicted by these two mechanisms.

However, the interannual variability in ERA5 and inter-experiment differences in the absorbed shortwave at the different stages of the seasonal cycle cannot explain the changes

over precipitation. Moreover, no significantly positive correlation is found between the shortwave absorption at the surface and precipitation at any lags but rather a strong anticorrelation signal is found, which is a result of stronger convective activity leading to more cloud cover and less downwelling shortwave at the surface. Therefore, while this chapter found some evidence of strong correlations between SW and precipitation, there is little evidence found that the SW drives precipitation, as argued by the solar declination angle mechanism.

Cloud-radiative effects (CRE) are known to be key for precipitation in monsoon regions and the central argument of Magaña et al. (1999) is that precipitation and CRE (at the surface) are part of a feedback mechanism that explains the MSD. This chapter presents the first regional evaluation of the net CRE at the surface as well as the long-wave and short-wave contributions. The net CRE at the surface over the wet season is negative in the regions of high precipitation, i.e., the East Pacific ITCZ and the MSD region reaching values of -100 W m^{-2} over the core ITCZ region in both the models and ERA5.

The net CRE is dominated by the short-wave component that acts to cool the surface due to the effect of cloud cover associated with convection. Over the MSD region, the net, shortwave and longwave CRE at the surface show a bimodal regime that closely follows the evolution of precipitation. Finally, an experiment part of CFMIP in which the long-wave effects of clouds are turned-off from the radiative scheme shows that the longwave radiative effects are key for monsoon precipitation in Central America and southern Mexico, where longwave effects are decoupled from the simulation, shows that the long-wave component of CRE are key for sustaining the monsoon circulation and precipitation irrespective of the bimodal MSD signal.

This section showed that CRE have a strong seasonal cycle associated with the MSD in ERA5 and the MOHC experiments. However, further research into CRE in present and future climates in the region is warranted, for example, further work could include a detailed examination of the CRE at the top of atmosphere and at the surface in the MSD, particularly to understand the relationship between CRE and the large-scale circulation, and how this relationship is different over land in Mesoamerica than over the Caribbean Sea and the East Pacific Ocean.

One alternative hypothesis is that the MSD is caused by the modulation of the transport of moisture by the CLLJ (Herrera et al., 2015; Zermeño-Díaz, 2019; Martinez et al., 2019). The integrated moisture flux convergence and the total column water content are found to better explain observed and simulated differences in precipitation, compared to the previous hypotheses. Evidence is presented that the low-level wind flow variations on the west coast of Central America is linked to the variations in the strength and direction of the CLLJ. Changes to the CLLJ and moisture convergence allow skillful predictions of precipitation changes at the end of the MSD period but these are less skilful for changes at the start of the MSD.

A moist static energy (MSE) budget is implemented to investigate whether this technique could provide additional insight into the mechanisms of the MSD. The total column MSE, as well as the vertical advection terms of the budget show a clear bimodal signal that closely follows that of precipitation. The vertical advection of dry and moist static energy are found to have the strongest relationship to the interannual variability and the inter-experiment differences of precipitation in the MSD region. In particular, $\langle \omega ds/dp \rangle$ is able to better explain interannual variability in ERA5 as well as the precipitation differences between the range of experiments considered in this chapter.

The horizontal advection term does exhibit strong variations during the wet season over land and over the ocean, with increased divergence of h during the MSD, suggesting that the moisture transport hypothesis may be more relevant than the other theories. However, further research is required to better understand whether the vertical velocity profile changes during the rainy season or whether the strong relationship between the vertical advection term and precipitation is best explained by changes to the vertical profiles of h and s , as well as more research on how the horizontal advection term may be related to the CLLJ.

The findings of this chapter support the CLLJ hypothesis more than the earlier two hypotheses which rely on radiative-thermodynamic mechanisms. Variability of the CLLJ and its influence over the regional moisture transport seem to be key for other aspects other than the MSD (Durán-Quesada et al., 2017; Sierra et al., 2021). For example, evidence that the flow from the Caribbean Sea over the orography of the Mesoamerican region modulates convective activity in tropical cyclones (Fu et al., 2021), as well as the role of the CLLJ in teleconnection mechanisms from the Madden Julian Oscillation (MJO) (Martin and

Schumacher, 2011; Perdigón-Morales et al., 2019) highlight the relevance of the low-level jet in the dynamics and precipitation variability. In short, our results agree with recent work (Boos and Pascale, 2021; Fu et al., 2021) that suggests a larger role for mechanical forcing than radiative-thermodynamic effects in modulating precipitation variations in the region.

7

The tropical route of QBO teleconnections in a GCM

This chapter examines the influence of the stratospheric QBO on the tropical troposphere by, first, demonstrating a robust QBO signal in the pre-industrial control experiments of CMIP6 of the MOHC models. The mechanisms for this QBO signal are then explored using targeted model experiments with relaxation of the zonal wind toward observations. The findings of this chapter are discussed in the context of existing hypotheses of physical mechanisms that could explain a tropical route of QBO teleconnections.

7.1 Introduction

Long-distance effects or teleconnections associated with the stratospheric quasi-biennial oscillation (QBO) have been well documented in the subtropics and extratropics, for example for the stratospheric polar vortex (Holton and Tan, 1980; Anstey and Shepherd, 2014; Lu et al., 2020), the subtropical jets (Garfinkel and Hartmann, 2011; Hansen et al., 2016; Ma et al., 2021) and the North Atlantic Oscillation (Hansen et al., 2016; Gray et al., 2018; Andrews et al., 2019b). Observational and modelling evidence suggests that there is also a tropical route of influence of the QBO through impacts on monsoons (Giorgetta et al., 1999; Claud and Terray, 2007; Liess and Geller, 2012), the Intertropical Convergence Zone (ITCZ)

(Gray et al., 2018), tropical sea-surface temperatures (SSTs) (Garfinkel and Hartmann, 2011; Huang et al., 2012), cloud fraction or height (Liess and Geller, 2012; Peña-Ortiz et al., 2019), tropical cyclones (Ho et al., 2009; Jaramillo et al., 2021) and most prominently, the MJO (Son et al., 2017; Lee and Klingaman, 2018; Wang et al., 2019; Martin et al., 2021b).

The tropical route of QBO teleconnections remains less well understood than other routes for various reasons, see Haynes et al. (2021) and Hitchman et al. (2021) for recent reviews on stratosphere-troposphere coupling in the tropics. The short observational record limits the confidence in any analysis that seeks to investigate differences between the two QBO phases in a 30-40-yr long dataset, as variability in the tropics on QBO time-scales is dominated by ENSO (Liess and Geller, 2012; Seo et al., 2013; Gray et al., 2018). Similarly, the modulation of the location and magnitude of convection in the tropical Pacific by ENSO events can influence the characteristics of the QBO itself (Taguchi, 2010; Schirber, 2015; Christiansen et al., 2016; Serva et al., 2020), which makes it difficult to separate the cause and effects of ENSO and the QBO.

The observational evidence available has shown surface impacts associated with the QBO over monsoon and oceanic regions in satellite-derived fields such as cloud height, occurrence and OLR (Collimore et al., 2003; Liess and Geller, 2012), as well as in surface precipitation diagnosed from gridded datasets or from reanalysis (Seo et al., 2013; Gray et al., 2018). This observational evidence shows zonally asymmetric impacts, indicative that the impact of the QBO is not consistent across all the equatorial latitudes but rather depends on longitude, which has been suggested (e.g. by Collimore et al., 2003; Liess and Geller, 2012) to be due to a QBO modulation of the Walker circulation, which has been shown in some reanalysis (Yamazaki et al., 2020; Hitchman et al., 2021).

Modelling evidence for a QBO downward impact on tropical deep convective features also exist, for e.g., Giorgetta et al. (1999) found that boreal summer monsoon regions exhibit a significant response in cloudiness to the QBO winds in a GCM. In a cloud-resolving model, Nie and Sobel (2015) found that the influence of the QBO may depend on the strength of convection and the mean background SSTs, suggesting a non-linear effect of the QBO over a convective profile. However, only a relatively small number of studies have analysed tropical QBO teleconnections in CMIP5/CMIP6 models (Serva et al., submitted), as most

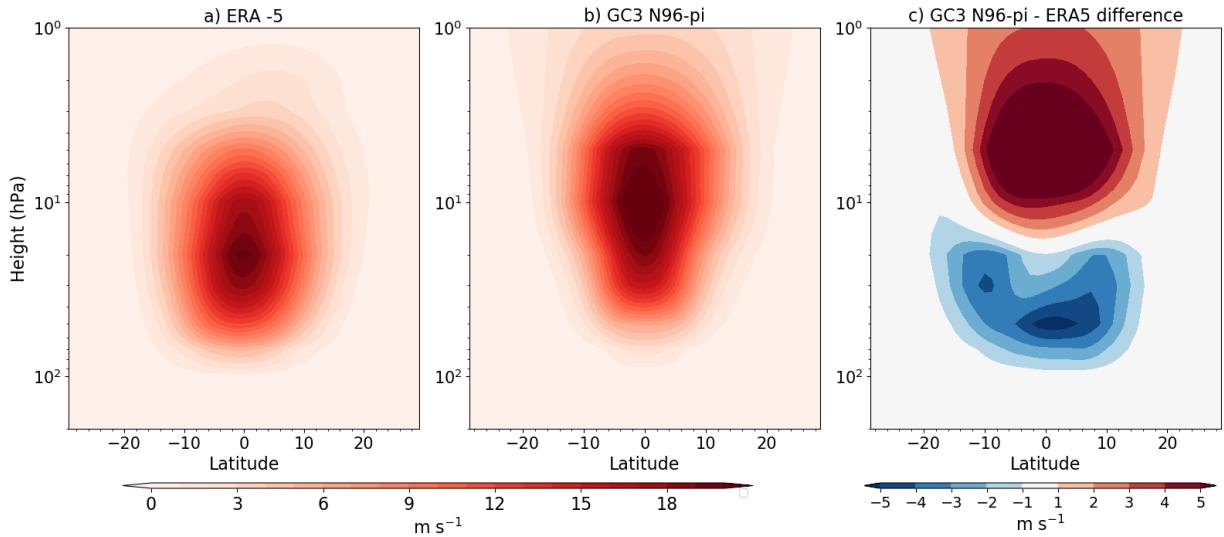

Figure 7.1: Latitude-pressure plot of the amplitude [m s^{-1}] of the QBO for (a) ERA5 and (b) GC3 N96-pi. (c) The difference in amplitude between the (b) model and reanalysis. Obtained from the zonal mean zonal wind fourier spectrum magnitude within the QBO periods, as in Schenzinger et al. (2017).

CMIP analyses focus on the overall representation of the QBO and teleconnections to the extra-tropics (Richter et al., 2020; Anstey et al., 2021).

The physical mechanisms through which the QBO could influence tropical surface climate are also not well understood (see section 2.5.2). The influence of the QBO over the temperature and vertical wind shear near the tropopause layer (Tegtmeier et al., 2020b; Martin et al., 2021c) has been hypothesized to affect convection through several mechanisms (Haynes et al., 2021). Early studies (Gray, 1984; Collimore et al., 2003) suggest that changes caused by the QBO to the vertical wind shear or static stability in the upper-troposphere lower-stratosphere (UTLS) region modify the depth of convection at equatorial latitudes. However, other studies suggest that the surface impact of the QBO may be a function of both the UTLS temperature changes and the tropospheric convective forcing (Nie and Sobel, 2015).

The leading hypothesis to explain an impact from the QBO on tropical deep convection suggests that changes to the UTLS static stability, caused by the QBO residual circulation, modifies the strength of convection (Collimore et al., 2003; Liess and Geller, 2012; Nie and Sobel, 2015; Yamazaki et al., 2020). However, most of the existing climate models underestimate the amplitude of the QBO in the lowermost stratosphere (Figure 7.1) and by

consequence the variability of the UTLS static stability associated with the QBO is lower in state-of-the-art GCMs than in the observed record (Schenzinger et al., 2017; Richter et al., 2020; Bushell et al., 2020). This bias has been suggested as a possible reason for the inability of current GCMs to reproduce the observed relationship between the QBO and the MJO (Lee and Klingaman, 2018; Kim et al., 2020).

The stratospheric biases in GCMs have led several studies to perform experiments in which the model stratosphere is relaxed towards an observed or idealized state, more commonly known as nudging (e.g. Garfinkel and Hartmann, 2011; Lee and Klingaman, 2018; Gray et al., 2020; Richter et al., 2020; Martin et al., 2021a). The nudging technique has proven useful because the relaxation can remove biases, identify causal pathways and test specific hypotheses regarding mechanisms (Gray et al., 2020; Martin et al., 2021a; Haynes et al., 2021). In particular, the nudging technique has been suggested as a potential tool to better understand observed relationships between the tropics and the QBO (Lee and Klingaman, 2018; Martin et al., 2021a).

In short, there is a lack of robust evidence for QBO surface impacts in the tropics, due to the limited observational record and the relatively scarce modelling evidence, particularly with GCMs, of QBO impacts on tropical climate. The Met Office Hadley Centre (MOHC) Unified Model (UM) extends to the mesosphere and includes a self-generated QBO via a non-orographic gravity wave scheme that compares well to observations, except for the weak amplitude bias in the lower stratosphere (Richter et al., 2020). Moreover, nudging has been successfully applied to this model in previous studies (Telford et al., 2008; Gray et al., 2020). For these reasons, this chapter uses the UM to investigate whether there are any surface impacts in the tropics associated with the QBO and what mechanisms may be at play in the observed stratospheric-tropospheric coupling.

This chapter first investigates whether there are any robust connections between the QBO and the tropical troposphere in the MOHC model, using the CMIP6 pre-industrial control simulations. This analysis benefits from the extremely long simulations that can provide improved estimates of statistical significance when compared with the relatively short observational datasets. The first part will demonstrate robust links between the QBO and several features of tropical climate but no conclusive statement can be made on

the direction of causality using these simulations. For that reason, nudging experiments feature in the second part of the chapter. Atmosphere-only and coupled ocean-atmosphere model simulations are analysed to evaluate the effect of improving the biases of the QBO amplitude on the surface response. Specifically, these experiments test the UTLS static stability hypothesis, so that stronger effects would be expected in a model with a stronger UTLS temperature variability associated with the QBO compared to a model with a weaker UTLS static stability variability.

The methodology and data used in this chapter are described in section 7.2, including details of the nudging experimental setup. Then, the QBO impacts diagnosed in the CMIP6 experiments are presented in section 7.3. Section 7.4 examines the results from the nudging experiments. A discussion and conclusions are presented at the end of the chapter.

7.2 Methods and data

The observational datasets and reanalysis (ERA5) used in this chapter are described in more detail in section 3.1 and consist of the HadSST3 dataset for SST, GPCP and GPCC for precipitation and ERA5 for the rest of the diagnostics that include the zonal and meridional winds, air temperature and vertical velocity.

7.2.1 CMIP6 data

In section 7.3, three pi-control experiments are analysed: HadGEM3 GC3.1 at N96 and N216 horizontal resolutions (hereafter referred to as GC3 N96-pi and GC3 N216-pi) and UKESM at N96 horizontal resolution (hereafter referred to as UKESM N96-pi). The N96 and N216 atmospheric resolution is $1.875^\circ \times 1.25^\circ$ and $0.83^\circ \times 0.56^\circ$, respectively whereas the oceanic resolutions are 1° (ORCA1) and 0.25° (ORCA025), respectively. The full 500 years available of the GC3 N216-pi simulation are used and although more data exists for UKESM-pi and GC3 N96-pi, we use 500-yrs of these simulations as well for consistency. The three simulations chosen use the same model setup, with constant year 1850 forcing, but differ in their horizontal resolution or the treatment of aerosol-chemistry processes and land-surface interactions (see section 3.2). The CMIP6 version of the model extends to the

lower mesosphere and includes a self-generated QBO via a non-orographic gravity wave scheme that compares well with the observed QBO (Richter et al., 2020).

Pre-industrial control experiments are ideal for the purpose of examining the mechanisms of internal variability of a model because external forcing is kept constant throughout the long integrations (e.g. in CMIP6 these experiments are at least 500 years long). For these reasons, multiple studies have used this type of experiments to investigate teleconnections and variability on multiple time-scales isolated from the influence of external forcing (see e.g. Watanabe et al., 2012; Zanchettin et al., 2014; Palmer and McNeall, 2014; Menary et al., 2018; Dimdore-Miles et al., 2021; Villamayor et al., 2021). For the purposes of this chapter, the model variability on QBO-frequencies which samples several states of decadal variability is compared against the observed variability.

The majority of the diagnostics in section 7.3 are shown for the higher resolution GC3 N216-pi simulation and comparisons with the other two simulations are noted where appropriate. The equatorial climate of GC3 N216-pi captures tropical dynamical processes and tropical mean and extreme precipitation reasonably well relative to lower-resolution configurations (Chapter 4, García-Franco et al., 2020; Abdelmoaty et al., 2021). This configuration has been top ranked amongst all CMIP5/CMIP6 models in metrics such as the seasonal-phase locking and amplitude of ENSO (Menary et al., 2018; Richter and Tokinaga, 2020; Liu et al., 2021), extreme precipitation (Abdelmoaty et al., 2021) and the annual cycle of equatorial Atlantic SSTs and low-level winds (Richter and Tokinaga, 2020). The HadGEM model has also been historically top ranked in representing the stratosphere and the QBO (Schenzinger et al., 2017; Richter et al., 2020). However, several biases are notable in this model, particularly in tropospheric dynamical features such as the southward bias of the Atlantic ITCZ linked to the dry Amazon bias and too strong precipitation rates over the East Pacific ITCZ (García-Franco et al., 2020).

7.2.2 Indices

For the QBO, the monthly-mean equatorially averaged [5°S-5°N] zonal mean zonal wind at 70 hPa is used and each phase of the QBO is defined using the threshold of 2 m s^{-1} (Garfinkel and Hartmann, 2010), so the westerly phase (QBOW) is defined for months with an index

value above 2 m s^{-1} and the easterly phase (QBOE) for index values below -2 m s^{-1} . For ENSO, the EN3.4 SST index [190-240°W, 5°S-5°N] is used, with a running-mean of 5 months and a threshold of $\pm 0.5 \text{ K}$ used to define positive or negative events (Trenberth et al., 1998). Neutral months are defined where the running-mean of EN3.4 index is smaller than $\pm 0.5 \text{ K}$.

The amplitude and descent rates of the QBO are calculated using the deseasonalized zonal mean zonal wind, as above for the QBO index but using model levels in the stratosphere. The amplitude (A) of the QBO is defined using the first and second principal components (PCs) empirical orthogonal function (EOF) decomposition of the equatorial 10-70 hPa wind time-series (Serva et al., 2020) as $A = \sqrt{PC1^2 + PC2^2}$. The descent rates are calculated following Schenzinger et al. (2017) for descending westerly and easterly phases individually by finding the level of the zero wind line ($u = 0$) for each month and computing the difference between consecutive months. These definitions of the amplitude and descent rates were chosen so that we can evaluate, e.g., the influence of ENSO on the whole profile of the QBO and not just one single level.

An index for the Indian Ocean Dipole (IOD) was also required and this chapter uses a convective precipitation index of the zonal gradient in the Indian Ocean (convective IOD Index), defined as the difference of the deseasonalized area-averaged convective precipitation between the western [50-70°E] and eastern [80-100°E] equatorial [10°S-10°N] Indian Ocean, which is in a similar region as the standard SST IOD index (Wang and Wang, 2014). This convective precipitation index is used to define IOD events with a 1 standard deviation threshold to define positive and negative events.

7.2.3 Analysis techniques

Composite analysis is the primary technique used in the study. For each month the QBO phase (QBO-E or QBO-W) and the ENSO phase (El Niño, La Niña or neutral ENSO phase) was determined as described above. Annual-mean and seasonal-mean composites were derived by computing weighted averages to account for differences in the counts of each month, i.e, to avoid a possible aliasing with the seasonal cycle. This means the composites were derived by weighting each monthly-mean by the number of samples that contribute

to the mean and then computing the seasonal or annual-mean average so that all months contribute equally and there is no seasonal effect due to, e.g., QBO or ENSO phase-locking.

The length of the pre-industrial control experiments is such that in GC3 N216-pi the total number of El Niño and La Niña years were approximately 120 years, or over 1500 months for each phase in the entire simulation, and over 2300 months for each QBO phase. For example, El Niño months found under QBOW were 626 and 392 under QBOE, whereas in the observed 1979-2018 period, 62 QBOW El Niño months and 36 QBOE El Niño months were diagnosed.

Linear regression analysis has proven useful to understand the effect of one or more aspects of the climate over a region or a time-series, and was used to investigate the surface impacts of the QBO in observations by Gray et al. (2018). A simple linear regression model can be written as:

$$Y(t) = X_0 + X_i(t)\beta_i + \epsilon, \quad (7.1)$$

where Y is the measured or dependent variable, X_0 is a constant coefficient, β_i is the regression coefficient between X_i and Y and ϵ represents random error or a residual. In all cases, the regression coefficient and residual were found using an ordinary least-squares (OLS) method. A multivariate regression model can be used to study the joint effect of two or more predictors over a variable (Y) such that the model can be written as:

$$Y(t) = X_0 + \sum_j^N X_j(t)\beta_j + \epsilon \quad (7.2)$$

where $X_j(t)$ is any predictor with an associated regression coefficient β_j . The multivariate regression will be used to separate the linear influence of the QBO and ENSO in section 7.3. As in previous studies (Gray et al., 2018; Misios et al., 2019), the regression coefficient can be rescaled to evaluate the total effect that a predictor (X_j) can have on the variance of the measured variable (Y) using the standard deviation (σ_j) and the maximum ($X_{j,max}$) and minimum ($X_{j,min}$) values of X_j so that the rescaled coefficient β'_j can be written as:

$$\beta'_j = \beta_j \frac{X_{j,max} - X_{j,min}}{\sigma_j}. \quad (7.3)$$

7.2.4 Nudging experimental setup

The GC3.1 configuration of the UM model is used (version 11.4) for the nudging experiments using a present-day climate setup where all external forcings, including greenhouse gas and aerosol emissions, are set constant to those of the year 2000. Both atmosphere-only and ocean-atmosphere coupled experiments were conducted for 35 years (1981-2015 model years). The atmospheric horizontal resolution was N96 ($1.875^\circ \times 1.25^\circ$) and the coupled experiments use an oceanic resolution of 0.25° (ORCA025) using the NEMO model (Storkey et al., 2018). The atmosphere-only (AMIP) experiments were run by prescribing the CMIP6 SST and sea-ice boundary conditions for the period 1981-2015 (that have been provided as part of the CMIP6 AMIP forcing setup), note the surface boundary SSTs are used at all latitudes.

For each of the configurations several ensemble members were launched (see Table 7.1). Each ensemble member was initialized from different ocean/atmosphere initial conditions in order to decrease the role that internal variability may have on these simulations. Specifically, the coupled ocean-atmosphere configuration was initialized using oceanic conditions from a long integration of the same model configuration that were found 10 years apart from each other.

The nudging technique used in this chapter refers to the relaxation of a model variable towards a specified state which can be from reanalysis, observations or idealized states (Gray et al., 2020; Martin et al., 2021a). In the UM setup, three variables can be relaxed, air temperature (T) and the zonal (u) and meridional (v) components of the wind. Because of the nature of the UM, the relaxation is applied at each grid-point, in contrast to other studies (e.g. Martin et al., 2021a) that employ a spectral model and only apply the relaxation to the zonal-mean component. Specifically, the UM uses a Newtonian relaxation technique (Telford et al., 2008; Gray et al., 2020) which sets the field to be relaxed (F) at each time-step through the following equation:

$$\Delta F = G\Delta t(F_{ndg} - F_{model}), \quad (7.4)$$

Table 7.1: Experimental setup indicating the model configuration, the period, ensemble members (Ens.) acronym and relaxation details.

Setup	Period	Ens.	Name	Nudging
Atmosphere-only	1981-2015	3	AMIP	ERA5. U-only 90 hPa
Atmosphere-only	1981-2015	2	AMIP-Control	No
Atmosphere-only	1981-2015	3	AMIP-Shifted	ERA5. U-only, 90 hPa. Relaxation shifted -1 year.
Coupled	1981-2015	6	Coupled Nudged	ERA5. U-only 90 hPa.
Coupled	1981-2015	2	Coupled Control	No.

where ΔF is the discrete change of F at each time-step, G is the relaxation parameter, Δt is the time-step size, F_{ndg} is the value of the field from the nudging data and F_{model} is the model value of the field at the last time-step (Telford et al., 2008).

The relaxation parameter G sets the strength of the relaxation and is linked with the relaxation timescale (τ) by $G = 1/\tau$. In the UM the nudging data is available every 6-h. Previous studies (Telford et al., 2008; Gray et al., 2020) have shown that a 6-h relaxation time-scale is sufficient to constrain the stratosphere in the model and so the same parameter was used for the simulations of this chapter ($G = \frac{1}{6} \text{ h}^{-1}$).

Furthermore, the nudging can be performed between specified vertical levels and in selected latitude/longitude regions with *tapering*. The tapering refers to a linear interpolation between the maximum G and zero nudging ($G = 0$). For example, a tapering of 4 vertical levels was applied in our simulations which means that there was a linearly increasing G from a bottom level with no nudging to the level where the specified G is implemented; the same linear interpolation works for latitudinal tapering.

The experimental design relaxes the zonal wind (u) in the model levels corresponding to 90 hPa to 4 hPa, with a tapering of 4 levels, which means that full nudging was only working from 70 hPa to 10 hPa. The nudging was done at all longitudes in the latitude band of 10°S-10°N with a latitudinal tapering of 10 degrees on both sides, which means that at 20°N the relaxation parameter was 0. The experimental setup aims to reasonably simulate the observed variability of the zonal wind leaving the meridional component of the wind and the temperature to respond freely within the model.

In addition to the nudged and control coupled and AMIP experiments (Table 7.1), we performed another type of atmosphere-only experiment. In the normal AMIP Nudged experiment, the SST driving data corresponds to the same year as the imposed zonal wind in the equatorial stratosphere that was observed in the real-world. To explore possible feedback processes between QBO winds and the SSTs, we performed an AMIP Shifted experiment, where the nudging data was shifted with a -1 year lag from the SSTs. In this experiment, e.g., the model year 1997 was run using 1997 SSTs but zonal winds in the stratosphere corresponding to 1996 of ERA5. In this way we have minimised any in-phase relationship between the QBO phase and the SSTs that might occur, for example, if the tropospheric response to the imposed QBO winds is sensitive to the imposed background SSTs, as the experiments of Nie and Sobel (2015) have suggested (see section 2.5.2 for further details). An alternative approach would be to *shuffle* the SSTs so that each year is run with randomly selected SSTs. However, since we are performing multi-year simulations shuffling has associated issues of how to join the randomly-selected SSTs at the year-boundary to form a coherent multi-year SST time-series. To avoid this issue we decided to simply shift the SSTs by one year so the QBO phase and SSTs were not aligned.

7.3 Teleconnections in the pre-industrial control experiments

The tropical precipitation response to the QBO phase is analysed in both observations and model simulations, first in the annual-mean and then by season (section 7.3.1). The potential for aliasing with the ENSO signal is investigated (section 7.3.2) and QBO-ENSO interactions are further explored (section 7.3.3), as well as QBO interactions with the Indian Ocean dipole (IOD). Finally, interactions between the QBO and the ITCZ, monsoons and the Walker circulation are identified and discussed in 7.3.4.

7.3.1 Precipitation

QBO composite differences in annual mean precipitation (QBO-W minus QBO-E) are shown in Figure 7.2 from the gridded GPCP observational dataset and from all three model

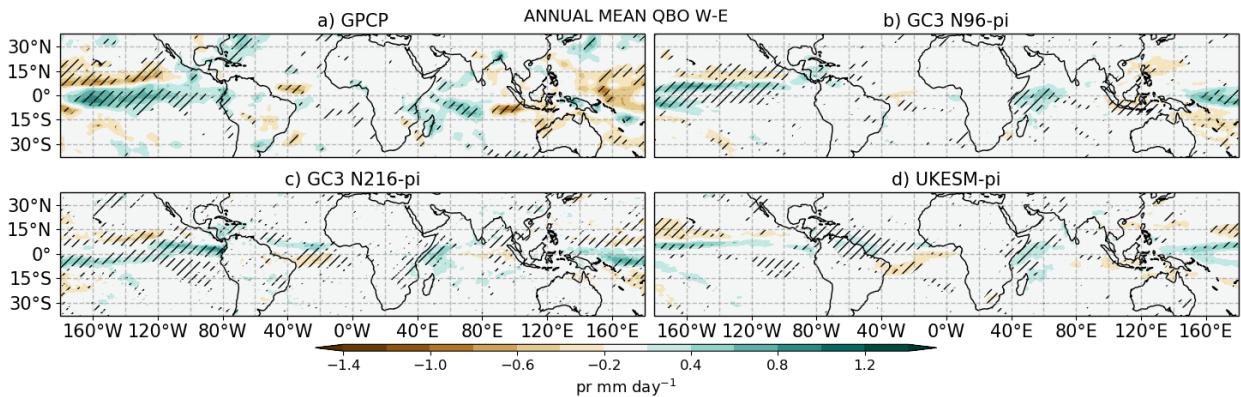

Figure 7.2: QBO-W minus QBO-E composite differences in annual-mean precipitation from (a) GPCP, (b) GC3 N96-pi, (c) GC3 N216-pi and (d) UKESM-pi. Hatching denotes statistically significant differences at the 95% confidence level using a bootstrapping with replacement test.

simulations. In the observations the QBO signals are largest and statistically significant in the tropical Pacific, equatorial Atlantic and Indian Oceans, in agreement with previous analyses (Liess and Geller, 2012; Gray et al., 2018). The three simulations agree reasonably well with the GPCP distributions and amplitudes, particularly in the Pacific and Indian Oceans. Positive differences of up to 1.2 mm day^{-1} are found in the equatorial Central Pacific and the Indian Ocean and negative differences of up to 0.6 mm day^{-1} in the off-equatorial North Pacific, although the differences are smaller in the simulations than observed.

In the tropical Atlantic, however, there is an indication of a weak but significant signal in the observations near the ITCZ but the models show a signal of the opposite sign in this region (or the absence of a signal in the case of GC3 N96-pi). This disagreement with observations may be due to the biased southward position of the Atlantic ITCZ in the model which is more pronounced in DJF (García-Franco et al., 2020).

The QBO signal in precipitation is found to be strongly dependent on the seasonal cycle in both models and observations. Figure 7.3 shows a comparison of the GPCP dataset and GC3 N216-pi for individual seasons. The positive equatorial Pacific signal in the GPCP dataset, which resembles an El Niño anomaly, is particularly strong and statistically significant in December-January-February (DJF) (Fig. 7.3a). A similar pattern is present in both March-April-May (MAM) (Figure 7.3c) but with no statistical significance. In GC3 N216-pi the QBO signal in the Pacific is significant in all seasons, likely due to

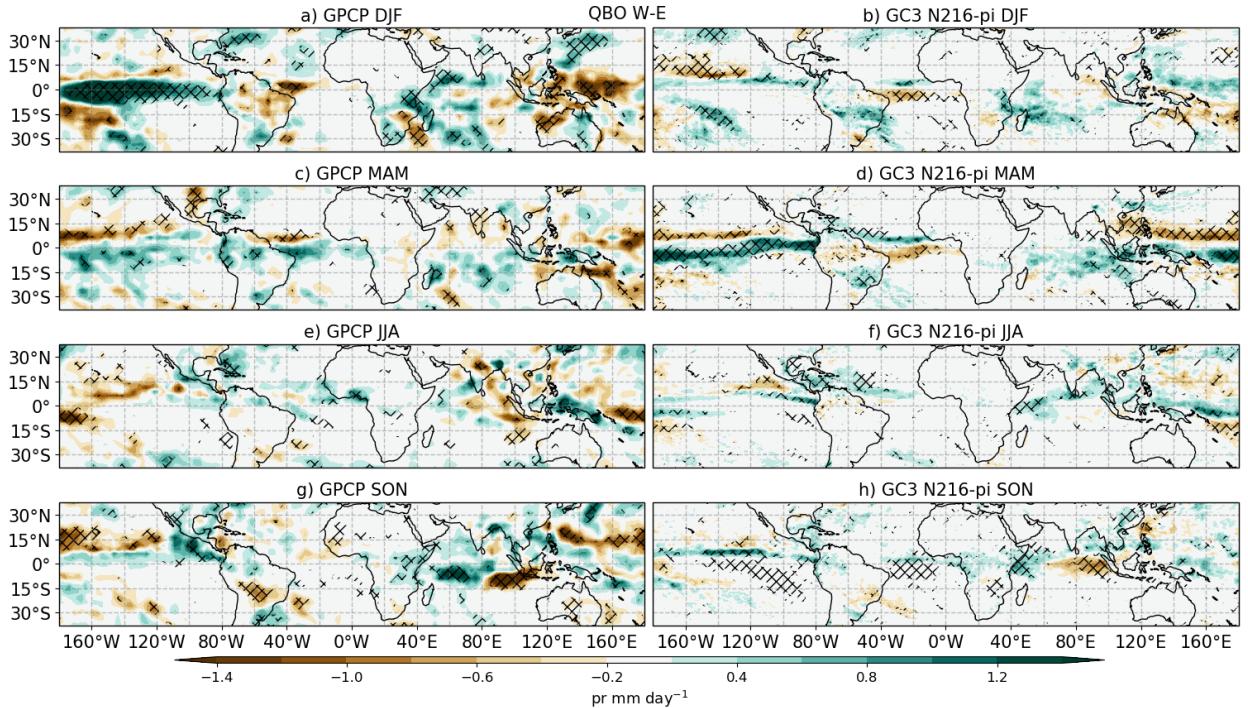

Figure 7.3: As in Figure 7.2, but showing seasonal-mean QBO composite from (left) GPCP and (right) GC3 N216-pi for DJF, MAM, JJA and SON from top to bottom.

the greater number of years in the ensembles, although it is shifted slightly compared to GPCP and is strongest in MAM (Fig. 7.3c).

In the Atlantic, the QBO signal in the ITCZ region is more clearly evident in the individual seasons. In DJF there is reasonable similarity between the model and observations but by MAM the opposite sign of the model compared to GPCP becomes evident, even though the ITCZ bias in the model is stronger in DJF than in MAM (García-Franco et al., 2020). In addition, all models and GPCP indicate that the Caribbean Sea is wetter in JJA during QBO-W than in QBO-E (see Fig. 7.3). In the Indian Ocean, the observations and all models show relatively large and significant differences in SON, (Fig. 7.3e-f), characterized by a dipole of wet anomalies to the west and dry anomalies to the east. The dipole anomalies suggest a possible QBO influence on the IOD, which is characterized by a zonal gradient of SSTs and convective activity in the Indian Ocean that is specially prominent in SON (Saji et al., 1999; Deser et al., 2010; McKenna et al., 2020). This possibility is explored further in section 7.3.3 below.

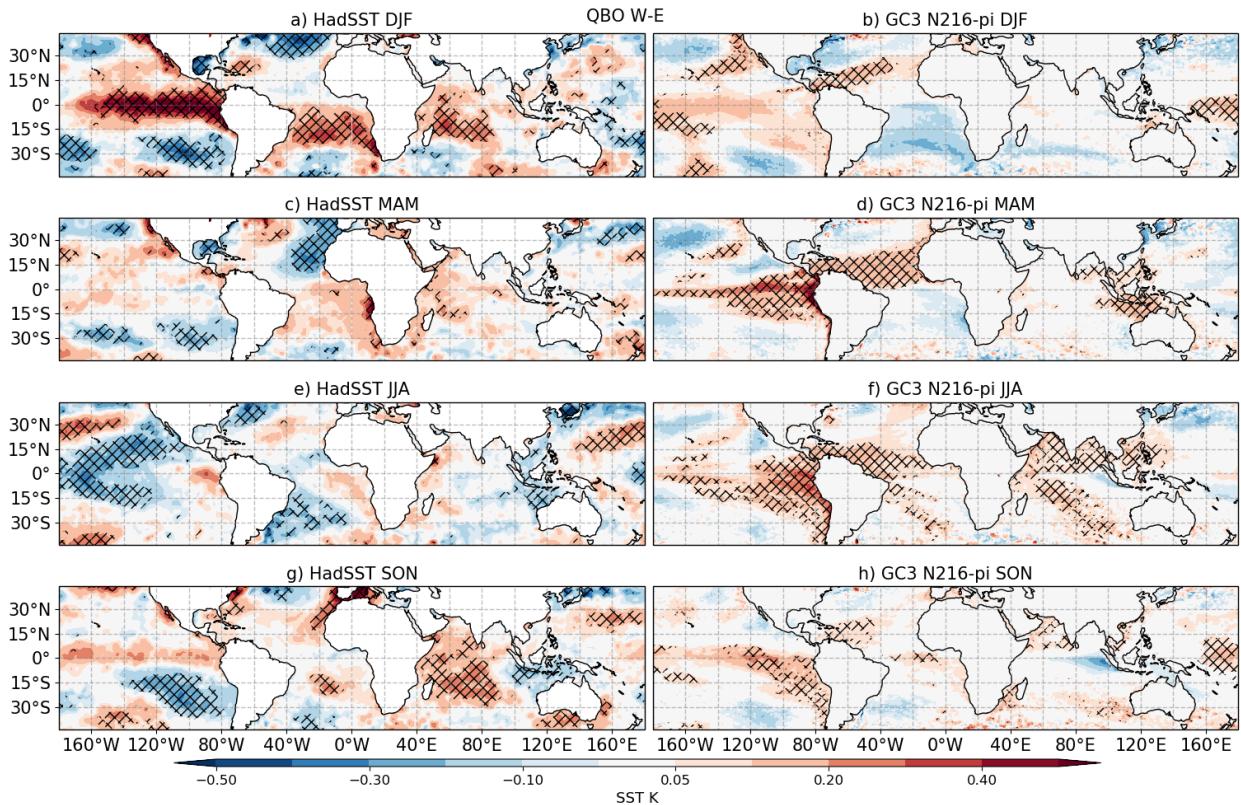

Figure 7.4: As in Figure 7.3 but for seasonal-mean sea surface temperatures from (left) the HadSST dataset and (right) GC3 N216-pi simulation.

In summary, the GPCP precipitation composite differences, characterized by a zonally asymmetric QBO signal that is primarily found over the oceans, are consistent with previous analyses (Liess and Geller, 2012; Gray et al., 2018), and the simulated QBO response patterns are in agreement with the observations. This agreement, together with the length of the model simulations (500 years) compared with the available observations, suggests that analysis of the modelled QBO signals may help to understand the mechanisms that give rise to the surface response in the QBO. However, the QBO signals from both model and observational analyses are very similar to well-known patterns for ENSO and the IOD. Previous observational studies have also shown a higher frequency of El Niño events during QBOW and of La Niña during QBOE in observations since 1979 (Taguchi, 2010; Liess and Geller, 2012), although the observational record is short so there is much statistical uncertainty. This potential for aliasing of the QBO and ENSO signals is investigated in the next section.

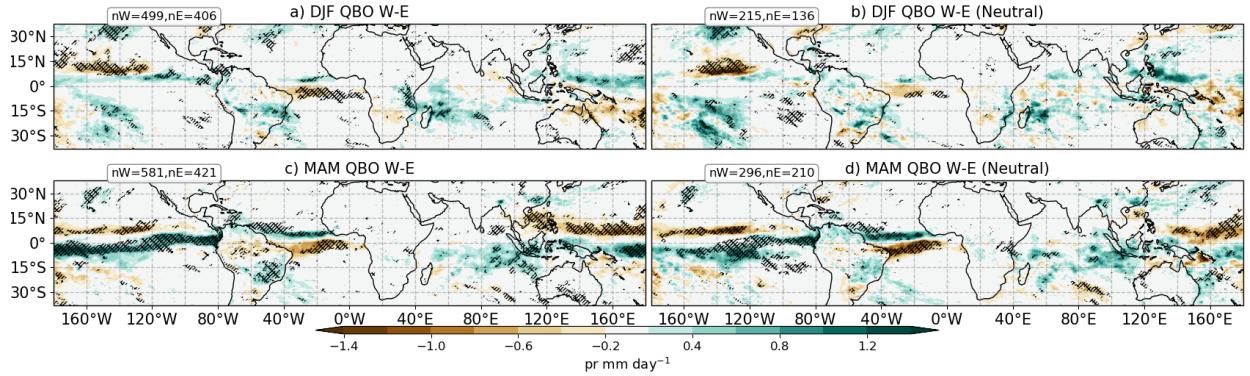

Figure 7.5: Composite QBO W-E differences of total precipitation in GC3 N216-pi in (a, b) DJF and (c, d) MAM for (a, c) all the events and (b, d) Neutral ENSO conditions only. The sample size of each composite is noted in the top left corner of each panel. Statistically significant differences to the 99% confidence level are shown through the hatching.

7.3.2 Potential aliasing of QBO and ENSO signals

To further explore the QBO signal and its interaction with ENSO, Figure 7.4 shows the QBO signal in SSTs. The QBOW minus QBOE composite differences are shown for individual seasons from the HadSST dataset and the GC3 N216-pi model simulation. The SST signals are consistent with the precipitation signals. Both model and observational datasets show significant positive SST responses in the equatorial Pacific that are similar to El Niño patterns. In the HadSST dataset the Pacific response is strongest in DJF and resembles an East Pacific (or 'standard') El Niño, whereas the simulated anomalies in DJF are weaker and look more like a central Pacific El Niño (Capotondi et al., 2015).

In GC3 N216-pi, the largest differences are observed in MAM in the easternmost Pacific Ocean and thus more closely resembles the observed DJF response pattern. In the South Atlantic the model shows a region of weak, insignificant cooling in DJF (Figure 7.4d), in contrast to the statistical significant warming signal in HadSST (Figures 7.4a,c). In the northern tropical Atlantic the model shows a year-long warming signal with stronger anomalies in MAM and JJA; this signal is present in HadSST but only found in JJA and SON and it is not significant (Fig. 7.4e, g). The simulated northern tropical Atlantic warm anomalies in DJF (Figure 7.4b) are accompanied by a warmer Caribbean Sea and a cooling of the Gulf of Mexico, warmer SSTs along the coast of California and a cooling of the central North Pacific, all of which resemble the impact of El Niño events and the

positive phase of the Pacific North American (PNA) pattern (Deser et al., 2010; Guo et al., 2017; Jiménez-Esteve and Domeisen, 2020).

As an initial investigation of the possibility of aliasing between the QBO and ENSO signals, Figures 7.5a,b shows the DJF QBOW minus QBOE composite differences of total precipitation from the GC3 N216-pi simulation using all years (as in figure 7.3) compared with using only those years identified as ‘ENSO-neutral’. Although the sample size is substantially reduced in the latter (see figure for the number of months in each QBO composite) the sample size is nevertheless still large. The response patterns are similar in each plot, which suggests that the QBO signal is unlikely to be the result of a sampling bias that favours one particular phase of ENSO.

An alternative approach to investigate the possibility of aliasing of the QBO/ENSO signals is to use a multi-linear regression technique (see section 2) in which the signal is analysed for both QBO and ENSO simultaneously. Here, we switch to analysing convective precipitation to better investigate the possible influence of the QBO on tropical deep convection.

Figures 7.6a,b show results from a simple linear regression analysis of the monthly-averaged time-series of GC3 N216-pi total precipitation in which a single QBO index is employed. Figure 7.6a includes all available years while Figure 7.6b includes only neutral ENSO years. The results are very similar to the annual-mean composite differences in total precipitation (7.2), with increased convective precipitation over the equatorial Pacific when the zonal winds at 70 hPa are positive.

Figures 7.6c,d show the ENSO and QBO signals when the Nino3.4 index is included as well as the QBO index. The ENSO response is clearly evident, highly statistically significant and compares well with the well-known patterns obtained from observations. The amplitude of the ENSO signal is also much larger than the QBO signal. Nevertheless, the QBO signal remains intact and all of the main features are still significant (Fig. 7.6c). For example, the positive regression coefficients that suggest a northward shift of the Atlantic ITCZ and the wetter Caribbean Sea and western Indian Ocean in the simple regression model are still found in the multivariate regression analysis.

These results suggest that the modelled QBO signal in total precipitation does not arise due to a simple aliasing of the signal with ENSO. However, the multi-linear regression

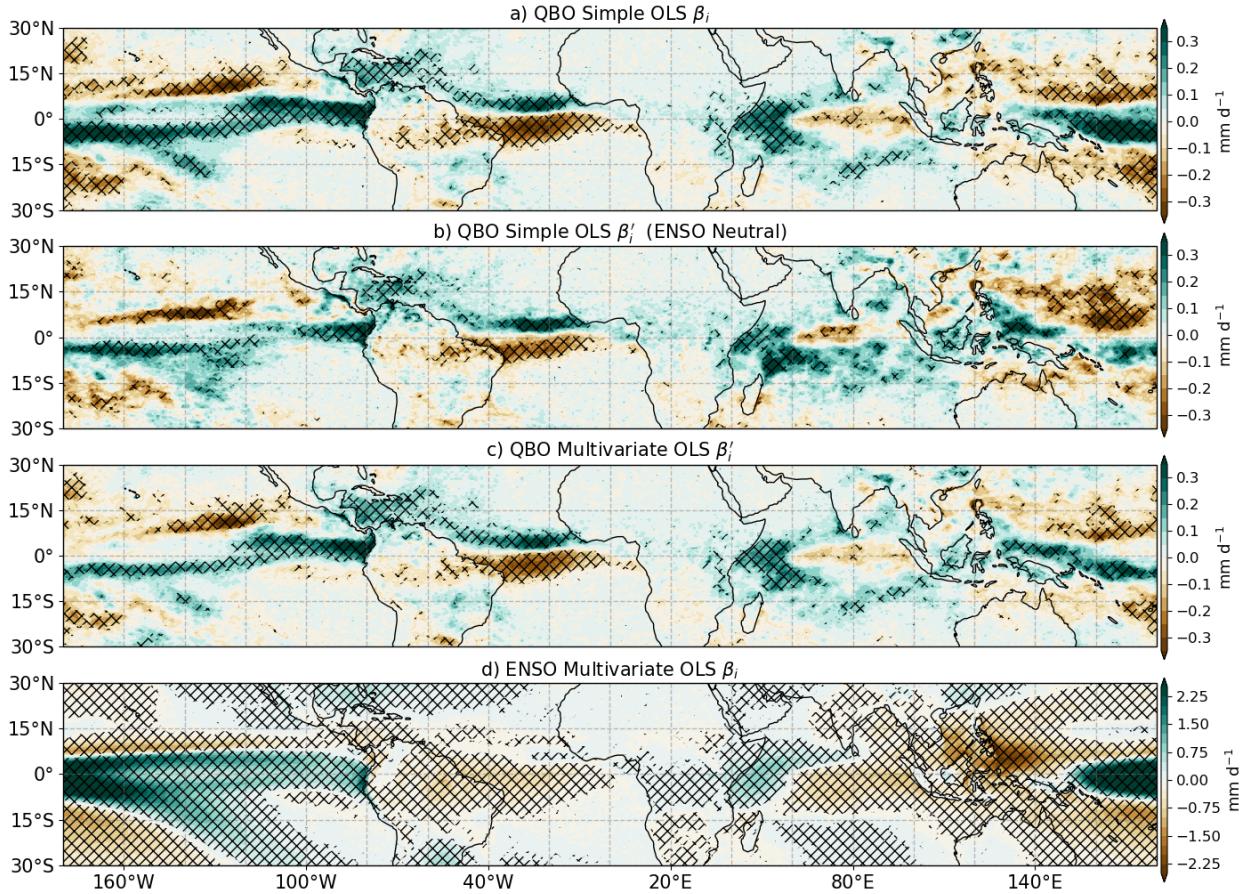

Figure 7.6: Annual-mean regression model results in GC3 N216-pi for convective precipitation. (a, b) Regression coefficients (β_i) from a simple ordinary least-squares (OLS) regression model with the QBO index for (a) all months and (b) ENSO-Neutral months only. (c, d) show the regression coefficients resulting from a multivariate regression model using the ENSO and QBO indices for the (c) QBO and (d) predictors. In all cases, the regression coefficients are rescaled by multiplying the regression coefficients with the ratio of maximum amplitude and standard deviation of the QBO or ENSO indices.

technique assumes that the QBO and ENSO indices are orthogonal and that their responses add together linearly. The similarity of the two responses indicate that this is clearly not the case and there is substantial interaction between the two phenomena. Nevertheless, the QBO signal remains even when only neutral-ENSO years are included in the analysis, suggesting that the QBO has a real influence on the surface precipitation.

7.3.3 Interaction of the QBO with ENSO and IOD

To further explore the interaction of the QBO and ENSO, we first investigate whether aspects of the QBO are influenced by ENSO events. This relationship could be a real possibility since

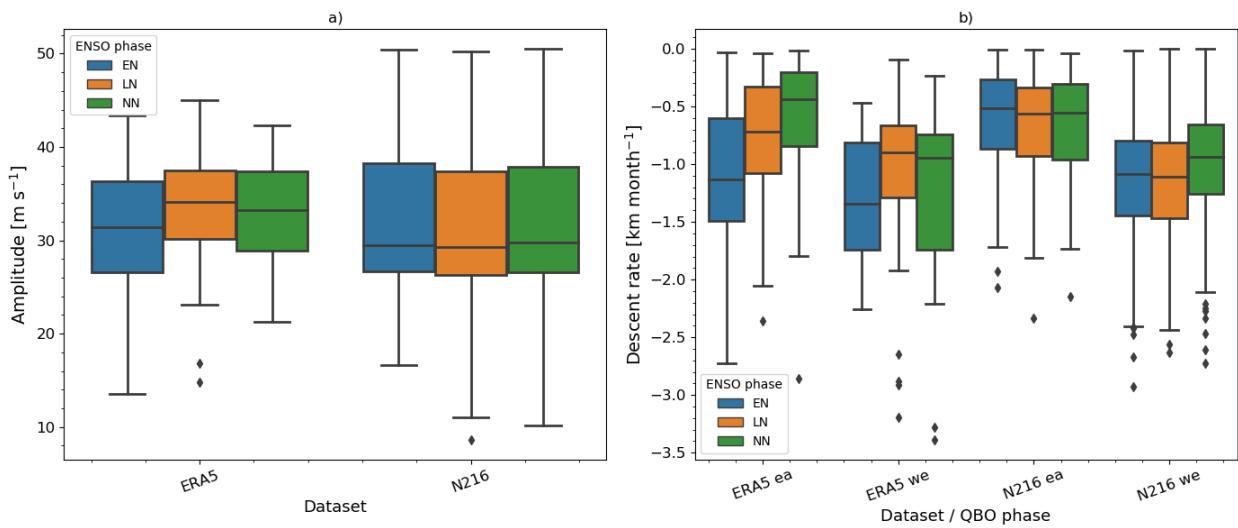

Figure 7.7: Box plots of QBO (a) amplitude [m s^{-1}] and (b) descent rate [km month^{-1}] separated by dataset (ERA5 and GC3 N216-pi) and ENSO phase. NN stands for Neutral ENSO. In (b) descent rates are shown for both descending easterly (ea) and westerly (we) phases following Schenzinger et al. (2017).

the intrinsic mechanism of the QBO involves tropical waves that are generated within the troposphere. Schirber (2015) found in a GCM that under El Niño conditions tropospheric wave activity increases and accelerates the downward propagation speed of the QBO westerly phase. However, the analysis by Serva et al. (2020) shows that only models with high resolution can reproduce the observed ENSO effects on the QBO amplitude while several models show no impact of ENSO on the QBO.

For that reason, we analyse several characteristics of the QBO and their dependence on ENSO phase, namely the descent rate and the amplitude of the QBO (see the 'Methods and Data' section for details of how the QBO amplitude is defined). The results are summarised in Figure 7.7 for the ERA5 reanalysis dataset (35 years; 1979 – 2014) and for the GC3 N216-pi simulation (500 years). In ERA5, the well-known faster descent rates during the westerly phase than in the easterly phase is clearly evident and agrees well with studies of longer datasets such as the Berlin radiosonde data (Schenzinger et al., 2017). Also, the ERA5 QBO descent rates and the amplitude both depend on the phase of ENSO. A higher amplitude and slower descent rates are observed during La Niña phases and weaker amplitudes and faster descent rates during El Niño.

Table 7.2: ENSO and IOD events frequency (month month⁻¹). For positive and negative events, for each mean value the error shown is the standard deviation of the probability density distribution (PDF) found by bootstrapping with replacement. Results in **bold** indicate that the event frequency PDF for QBOW is significantly different to QBOE to the 95% confidence level according to the KS test.

Dataset	QBO phase	El Niño	La Niña	IOD+	IOD-
GC3 N216-pi	W	0.24±0.09	0.19±0.05	0.17±0.03	0.11±0.02
GC3 N216-pi	E	0.21±0.07	0.26±0.07	0.12±0.03	0.15±0.03
ERA5/HadSST	W	0.28±0.01	0.27±0.02	0.17±0.01	0.13±0.01
ERA5/HadSST	E	0.17±0.02	0.27±0.03	0.12±0.01	0.19±0.03

In the model, the descent rates are also faster for the westerly than the easterly QBO phase, as observed, but the relationship between the QBO characteristics and ENSO is less clear. Neither the amplitudes nor descent rates of the QBO are significantly different between El Niño (EN) and La Niña (LN) phases. Interestingly, the only significant difference in the model is that descending westerlies are slower in Neutral ENSO months compared to EN or LN conditions, perhaps suggesting that tropical wave activity is increased in both ENSO phases compared with neutral years. The model results therefore suggest that there is little influence of ENSO on the descent rate and amplitude of the QBO in the GC3 N216-pi simulation. This finding of a null influence of ENSO on the QBO agrees well with the results of Serva et al. (2020) that examined these relationships in an older version of the HadGEM model. In summary, there is no evidence to suggest an influence of ENSO on the QBO in the model.

The reversed possibility, that the QBO may somehow influence ENSO events is now examined. A higher frequency of EN events during QBOW and of LN during QBOE has previously been noted (Taguchi, 2010; Liess and Geller, 2012) although the short observational record means that there is statistical uncertainty. In Table 7.2 we document the frequency of ENSO events in each QBO phase from the ERA5 reanalysis dataset and from the GC3 N216-pi simulation. Probability density functions (PDFs) were constructed for the model data using 36-yr samples with replacement and a Kolmogorov–Smirnov

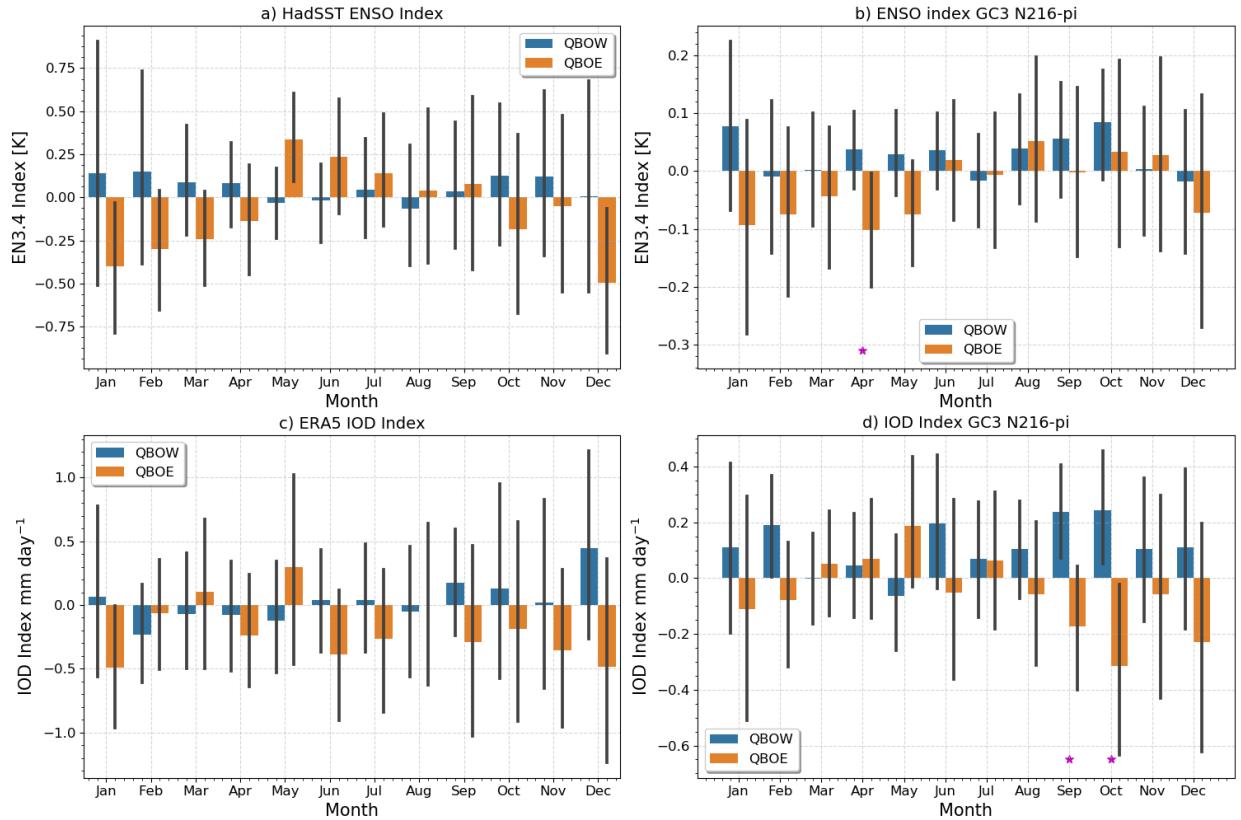

Figure 7.8: Monthly-mean (a-b) ENSO and (c-d) IOD-prc indices separated per QBO phase in (a, c) observations/reanalysis and (b, d) GC3 N216-pi. The error bars show the standard deviation of each index for each month and significant differences between QBO W and E months are highlighted with a * at the bottom of each panel.

(KS) test was used to evaluate if the PDFs of an event frequency (e.g. El Niño) were distinguishable for each phase of the QBO.

The results show significant differences for each ENSO phase in GC3 N216-pi (and this is also the case for the GC3 N96-pi and UKESM-pi simulations, not shown). El Niño events are more frequent under QBOW conditions than under QBOE in both observations and model datasets. La Niña events are equally frequent in both QBO phases in the HadSST dataset but in GC3 N216-pi they are more frequent under QBOE than under QBOW.

Figure 7.8a,b shows the EN3.4 index amplitude and interannual standard deviation as a function of each month from the HadSST dataset and the GC3 N216-pi simulation, separated for each phase of the QBO. From this we can examine, for example, whether any QBOW minus QBOE differences in ENSO characteristics arise primarily from one QBO phase or the other (i.e. a non-linear response) or whether both phases contribute

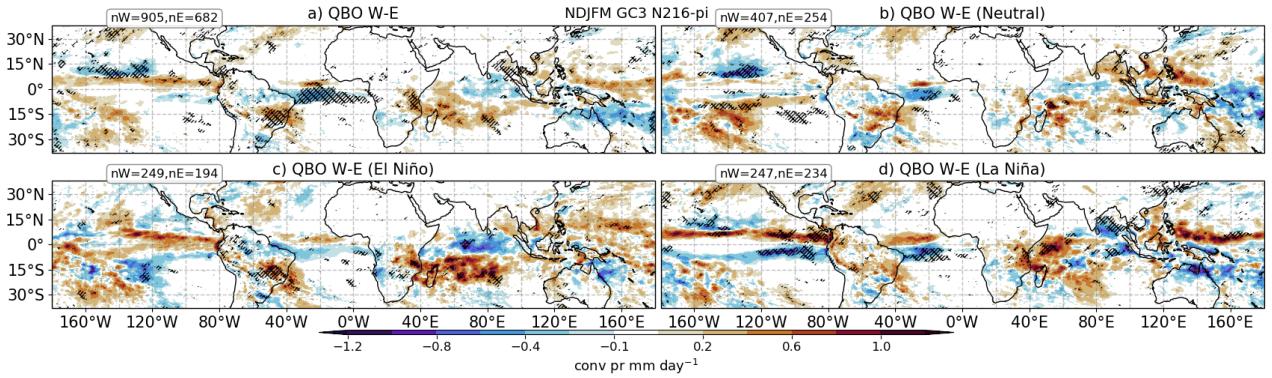

Figure 7.9: Composite QBO W-E convective precipitation differences in GC3 N216-pi in the peak ENSO season (NDJFM) for (a) all the events and (b) Neutral ENSO conditions only, (c) El Niño (EN) and (d) La Niña (LN). The sample size of each composite is noted in the top left corner of each panel. Statistically significant differences to the 99% confidence level are shown through the hatching.

equally to the response difference. There are significant QBO differences in EN3.4 SST in both the HadSST and GC3 N216-pi datasets. In particular, the mean ENSO indices are very frequently positive in QBOW and negative in QBOE months from September until January. In the model, the differences are largest from Feb-to-May (in good agreement with the results shown in Figure 7.3).

Figure 7.8 also suggests substantial non-linearities in the QBO-ENSO interactions, since the amplitude of the EN3.4 anomaly in each month under QBO E/W conditions is seldom equal and opposite. This non-linearity is also evident in Figure 7.9 where the QBO composite differences in convective precipitation during the peak ENSO season (November through to March) are shown using all years, only Neutral ENSO years and only EN or LN years. While the broad nature of the QBO signal remains similar, the details differ depending on the phase of ENSO (7.9c,d). For example, the Atlantic ITCZ response is most prominent in Neutral and LN phases (Figure 7.9c) whereas the eastern off-equatorial Pacific drier response is only found under Neutral ENSO years.

Positive differences in the western Indian Ocean and in the northern tropical Pacific are much stronger during LN (Fig. 7.9d) than in other ENSO phases. These results can be interpreted as EN and LN teleconnections being slightly different for each QBO phase. For example, in South America, more specifically in the South Atlantic Convergence Zone region (Jorgetti et al., 2014; Zilli et al., 2019), wetter conditions during QBOW compared to QBOE

are found in all years but this difference appears stronger during EN events. Similarly, the western Indian Ocean and eastern Africa show positive significant differences (W-E) during LN. These results suggest that in this model simulation, ENSO impacts to South America, Eastern Africa and the Indian Ocean are also dependent on the QBO phase.

Returning to Figure 7.8, during Dec-March in HadSST and Jan-May in GC3 N216-pi the QBO signal comes primarily from the QBOE phase, since the EN3.4 amplitudes are near zero under QBOW in these months. These results are consistent with the analysis of ENSO frequency in Table 7.2, which shows more frequent La Niña events under QBOE and El Niño events under QBOW. These results also suggest, therefore, that a stronger amplitude La Niña event in DJF may develop if there is a QBOE phase present in the lower stratosphere.

In the previous sections the precipitation and SST analyses also showed suggestive evidence of a relationship between the QBO and the IOD, in both the observations and the model. A link between the QBO and the IOD index and event frequency have been analysed in the same way as for the ENSO index and a significant relationship is confirmed (Table 7.2 and Figs. 7.8c-d). The model results indicate a more frequently positive IOD index under QBOW and a negative index for QBOE, and these differences are statistically significant in September and October. The GC3 N96-pi and UKESM-pi results are very similar (not shown) and the differences are also significant. The IOD event frequency is also markedly different depending on the QBO phase, with positive events more frequently observed in the westerly phase of the QBO and negative events found more frequently under QBOE, both for ERA5 and the model simulations (Table 7.2).

This section demonstrates statistically robust links between the IOD and ENSO, and the QBO. ENSO and the IOD are intertwined with pan-tropical teleconnections through zonal circulations (Cai et al., 2019), monsoons and the ITCZ. For that reason, the following section explores more closely the links between the QBO and features of the tropical circulation.

7.3.4 ITCZ, monsoons and the tropical circulation

This section investigates how the ITCZ, monsoons and the Walker circulation are influenced by the QBO in the model compared to the observations. Climate model biases in the representation of the migration and dynamics of the ITCZ, or in the mean-state of the

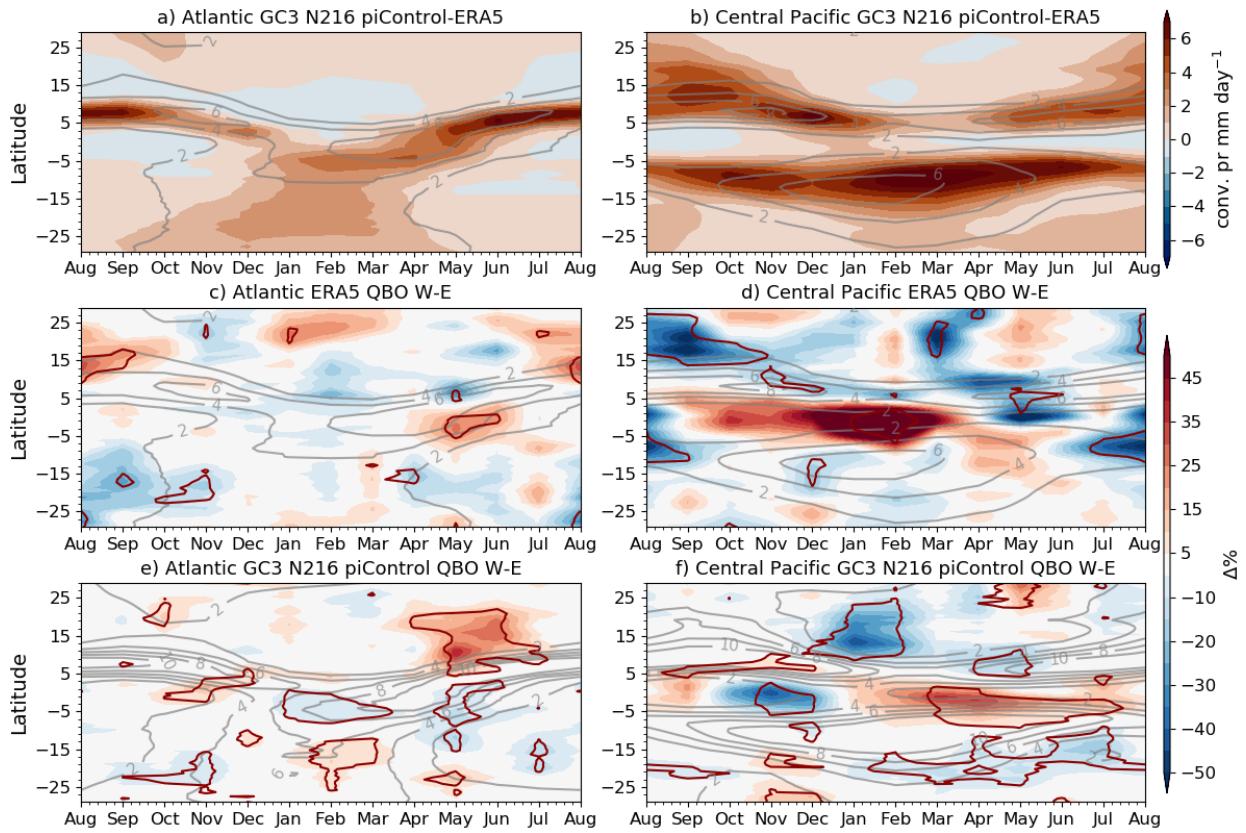

Figure 7.10: (a, b) Zonal mean biases in convective precipitation in GC3 N216-pi compared to ERA5 in the (a) Atlantic [60°W-20°W] and (b) Central Pacific [180°W-140°W] sectors. (c-f) Monthly and zonal mean QBO W-E percent (%) differences in convective precipitation where the absolute difference is weighted by the climatological value at each latitude and month. The line-contour (red) depict differences that are statistically significant to the 95% level according to a bootstrapping test and the grey lines show the climatological values.

Walker circulation, may modify any physical effects of the QBO over convection. For example, ITCZ biases in position or strength (Fig. 7.10a-b) are noteworthy in the model, and are mainly characterized by a southward shift of the simulated Atlantic ITCZ in DJF and MAM and a wider extent of the Central Pacific ITCZ compared to ERA5.

The monthly-mean QBO W-E zonal-mean convective precipitation differences in the Pacific and Atlantic ITCZ regions (Figure 7.10) show that the ITCZ impacts are seasonally dependent. While there are no clear differences in the Atlantic sector for ERA5 in any month, in GC3 N216-pi there is a significant northward shift of the ITCZ from April to June, which is likely associated with the warm SST anomalies found in this season in the northern tropical Atlantic (Fig. 7.4).

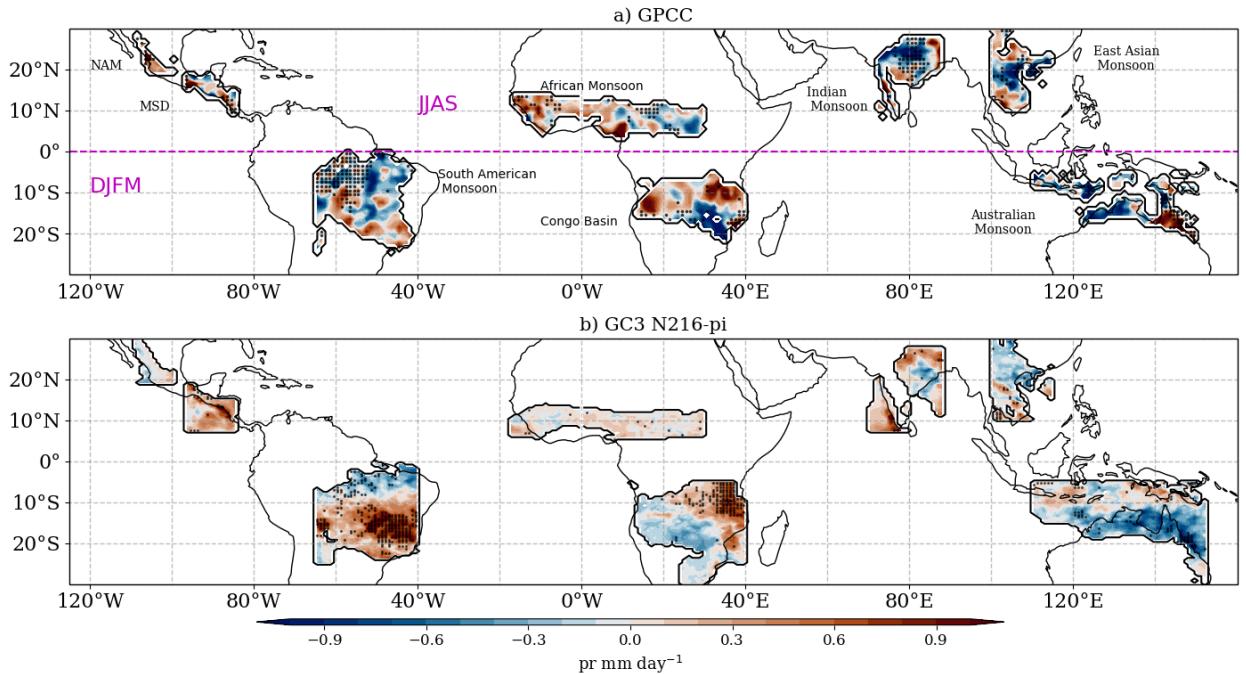

Figure 7.11: Convective precipitation differences in monsoon regions between QBO W-E phases for a) ERA5 and b) GC3 N216-pi. For monsoon regions in the Northern hemisphere, differences are shown for the JJAS period, whereas for Southern Hemisphere monsoons, results are shown for DJFM. Red dots indicate differences that are statistically significant to the 95% level according to the bootstrapping test.

The differences in the Pacific sector confirm previous model and observational results (Gray et al., 2018; Serva et al., submitted) that the Pacific ITCZ becomes stronger during QBOW compared to QBOE (Fig. 7.10d, f). In observations, the strongest differences are found during DJF, characterized by increased precipitation over the climatological position of the ITCZ. In GC3 N216-pi, a stronger ITCZ is observed slightly south of the climatological position from February to July, maximized in the MAM season. Very similar results for the Atlantic and Pacific sectors were observed for the other two simulations (not shown). The result also holds for ENSO Neutral periods (not shown) which rules out the possibility that the Atlantic ITCZ results are due to ENSO teleconnections to the tropical north Atlantic (Hastenrath, 2006).

In spite of existing observational evidence (Collimore et al., 2003; Liess and Geller, 2012; Gray et al., 2018) that suggests a link between the QBO and monsoon regions, the results in the previous sections (Fig. 7.2) show little-to-no effect of the QBO on precipitation over land in the simulations. The precipitation response over land is examined more closely by

analysing regions that fit the concept of the global monsoon. For this purpose, a monsoon region is defined as a region in which over 55% of the total annual rainfall is observed or simulated in the respective summer season and the summer-winter rainfall rate difference is higher than 2 mm day^{-1} (Wang and Ding, 2008; Wang et al., 2017, 2021).

After defining these regions, the QBO W-E differences are computed for JJAS and DJFM for Northern and Southern Hemisphere monsoons, respectively. Figure 7.11 shows that there is no coherent response to the QBO phase in GPCC in any monsoon region. However, in GC3 N216-pi there are significant differences for Southern Hemisphere monsoons. In the South American monsoon region, the QBO W-E differences indicate a significantly wetter region in South America, where the South Atlantic Convergence Zone is located (Carvalho et al., 2004; Jorgetti et al., 2014). Similarly, a drier Australian monsoon and wetter conditions for East Africa are observed during QBOW compared to QBOE.

For Northern Hemisphere monsoons there are no robust or significant differences (Fig. 7.11b). However, when only Neutral ENSO months are considered, all three simulations suggest a wetter Central American monsoon (not shown) in QBOW compared to QBOE. The different responses observed for the three simulations suggest that the representation of the dynamical features of each monsoon by each model configuration is important for any response to the QBO. Furthermore, the relatively smaller signals seen over land compared to over the oceans suggests that SST feedbacks are important for the QBO response in the model, so that reduced impacts are seen in regions of land convection.

A number of studies have suggested a link between the QBO and the Walker circulation to explain the zonally asymmetric nature of the QBO anomalies in convective precipitation (e.g. Collimore et al., 2003; Liess and Geller, 2012). To evaluate this hypothesis, the zonal streamfunction is used to measure the Walker circulation (Yu and Zwiers, 2010; Bayr et al., 2014) and is defined as:

$$\psi = 2\pi \frac{a}{g} \int_0^p u_D dp, \quad (7.5)$$

where ψ is the zonal streamfunction, u_D is the divergence part of the zonal wind, a is the Earth's radius, p is the pressure coordinate and g the gravitational constant. The

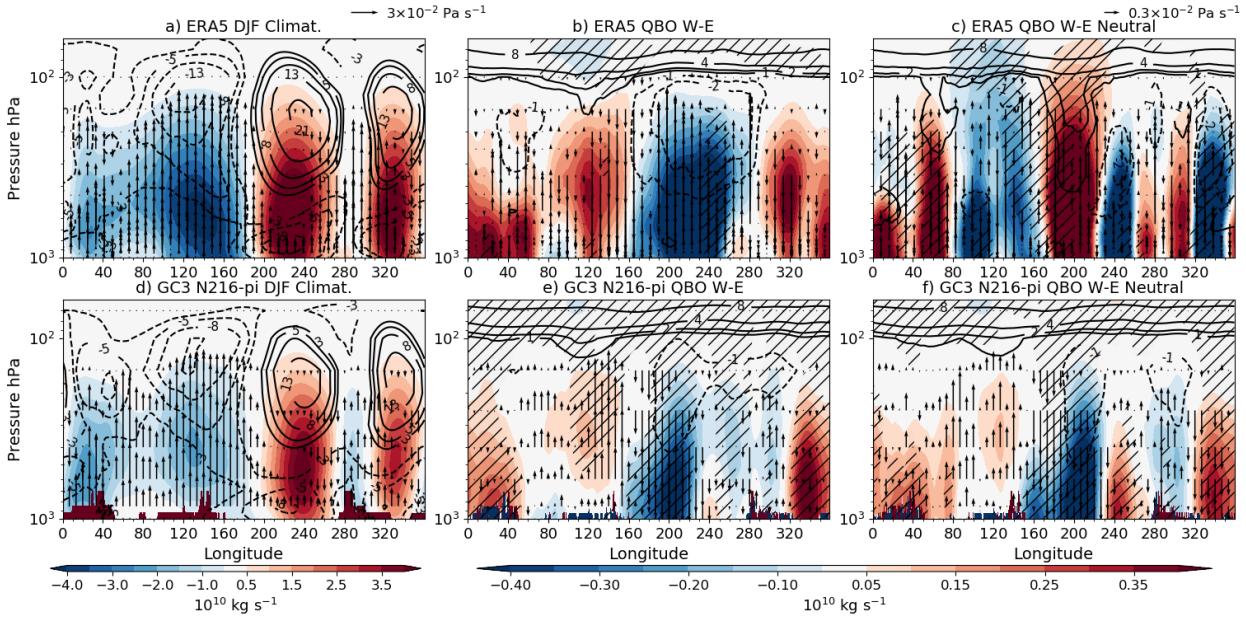

Figure 7.12: (a, d) Climatological mean-state of the Walker circulation, depicted through the zonal streamfunction (ψ) in shading, the zonal wind (contours), and vertical velocity (ω [Pa s^{-1}], vectors) during the DJF season in a) ERA5 and (b) N216-pi. (b, c, e, f) show W-E composite differences, during DJF, for the same variables only that hatching represents statistical significance to the 95% confidence level for differences in the streamfunction, and only statistically significant differences in the zonal wind and ω are shown. (g-h) are as in (d-f) but considering Neutral ENSO periods only. Example vector sizes for ω are given in the top right corners of a and c.

streamfunction is calculated by first averaging over the equatorial band of 10°S–10°N and integrating to the top level of each dataset.

QBOW minus QBOE composite differences in DJF show that the streamfunction in the eastern Pacific [220–260°E] is significantly weaker during QBOE than during QBOW in ERA5 and GC3 N216-pi (Fig. 7.12). These streamfunction differences are significant even low in the troposphere in the model. The zonal wind at upper-levels (300–100 hPa) is also weaker in QBOW compared to QBOE at 200°E in both model and reanalysis. In GC3 N216-pi, the negative ψ difference is accompanied by descending motion anomalies in the 170–220°E region, whereas anomalous ascent is observed in the Maritime continent and Indian Ocean. The differences in the other simulations agree with the results of GC3 N216-pi (not shown).

In boreal fall (Fig. 7.13), the differences are also significant and are linked to the relationships found between the IOD and the QBO. Specifically, significant positive differences in the streamfunction are found in the eastern Indian Ocean and maritime continent and

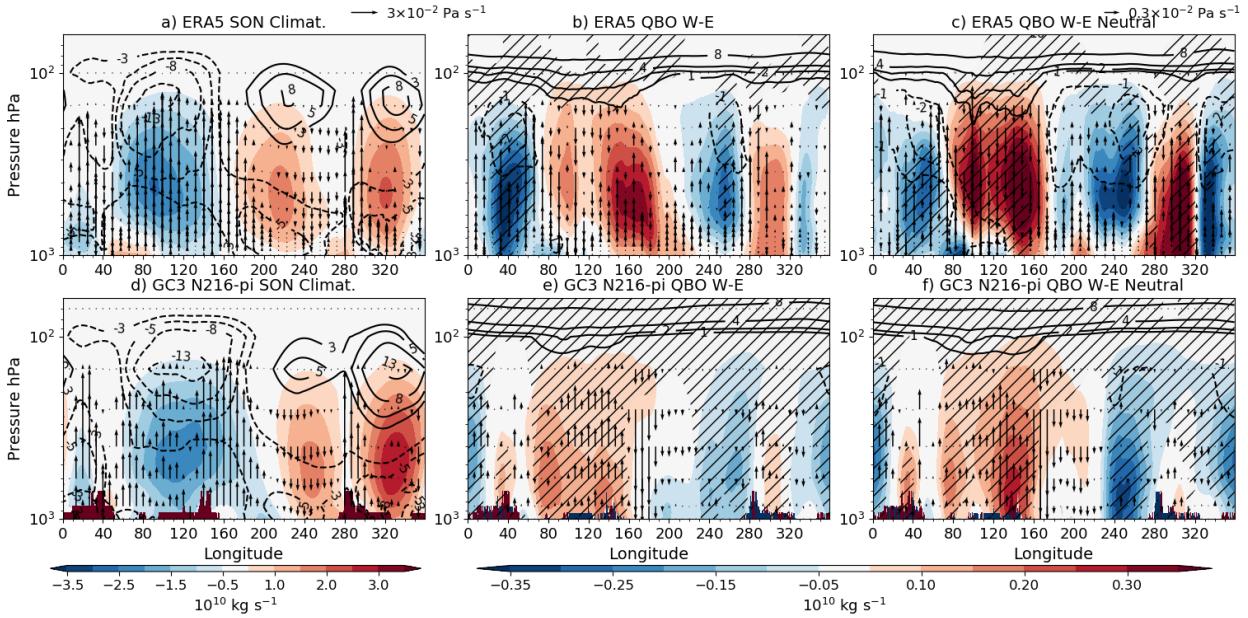

Figure 7.13: As in Figure 7.12 but for the SON season.

negative differences in the eastern Pacific. In GC3 N216-pi, vertical velocity anomalies indicate stronger ascent in the western Indian Ocean and in the Maritime continent whereas descending anomalies are found in the eastern Indian Ocean. These results agree with positive IOD indices found in QBOW and a mean negative index during QBOE.

The rightmost panels in Figures 7.12 and 7.13, in which only Neutral ENSO months are considered, suggest that this relationship between the QBO and the Walker circulation occurs regardless of ENSO events for GC3 N216-pi. However in ERA5, removing ENSO events changes the sign of the response, likely due to the small sample size in the observational record when only neutral months are considered. These results highlight links between the large-scale overturning circulation and local responses which may explain the zonally asymmetric results found in previous studies and in early sections of this chapter.

In short, robust surface and circulation impacts were diagnosed in the GC3 N216-pi model. To our knowledge, this is the first modelling study to have shown a QBO signal in tropical convective features that is not due to aliasing with ENSO within a GCM. For this reason, this model is a suitable tool for exploring QBO impacts in the equatorial troposphere at length using targeted model experiments.

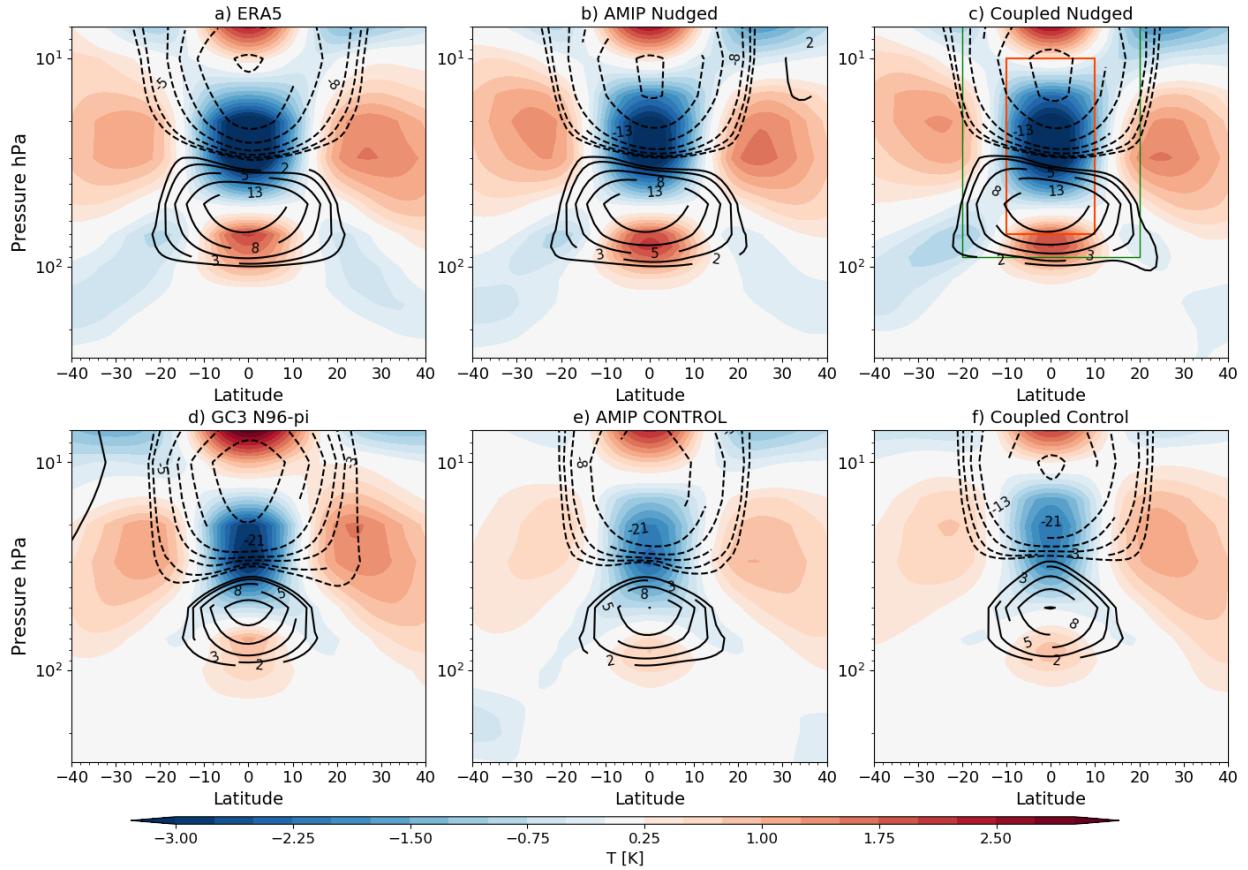

Figure 7.14: Latitude-height plot of the annual and zonal-mean temperature (shading) zonal wind (contours in m s^{-1} differences (QBO W-E) in (a) ERA5, the ensemble-mean nudged simulations in (b) AMIP and (c) coupled configurations and (d) GC3 N96-pi from CMIP6, the control simulations with no nudging for (e) AMIP and (f) coupled configurations. The black line denotes the tropopause height obtained from the model data in (b, d) and for ERA5 the tropopause height was found through the gradient threshold method. For the nudged experiments, the ensemble-mean is shown. The nudging region is illustrated in (c), where the red box indicates where the full nudging is applied and the green box illustrates the tapered region.

7.4 The nudging experiments

This section investigates results from a series of nudging experiments in which the equatorial zonal winds in various configurations of the HadGEM model were relaxed towards ERA5 (between 10°S - 10°N , full nudging was applied from 10 hPa to 70 hPa, tapering to zero by 90 hPa; see section 7.2.4 for full details). Nudging the QBO winds towards reanalysis at all grid-points in the model means that feedback from the modelled tropospheric processes onto the QBO is eliminated. Examination of the QBO signal in the troposphere and at the surface then allows an investigation of the mechanisms of QBO influence on the modelled

tropospheric or surface fields. Nudging the fields also serves to correct a bias in the equatorial lower stratosphere where the model underestimates the amplitude of the QBO.

The model has been run in both AMIP and coupled ocean configurations to explore the role of the ocean, since results from previous studies (Nie and Sobel, 2015) and from the analysis in the previous section show a dependance of the QBO signal on the underlying background SSTs. Additional AMIP sensitivity experiments are also performed, to further test the importance of consistency between SSTs and the QBO phase. Parallel Control simulations were performed for each experiment, identical in all respects apart from the nudging (see Table 7.1 for details of the experiments, including length of the simulations and numbers of ensembles performed). The experiments are then used to investigate the static stability hypothesis for the tropical route of QBO teleconnections with the surface.

Before proceeding to analyse the surface response, we first show the QBO impact in UTLS temperatures and zonal winds (Figure 7.14) from the nudged experiments compared to ERA5 and the 500-yr CMIP6 GC3 N96-pi simulation, as well as the Control experiments in which the QBO is free-running instead of being nudged. The QBO W-E differences in the nudged experiments closely resemble the ERA5 field, confirming that the nudging has been successful. Both temperature and wind differences are larger in the nudged experiments compared to the non-nudged experiments at all heights over the equator, especially in the region just above the tropopause between 70-90 hPa, confirming also that the weak QBO amplitude bias in the lower-stratosphere has been removed by the nudging.

7.4.1 Atmosphere-only experiments

This section describes the results of the atmosphere-only experiments: AMIP Nudged, AMIP Control and AMIP Shifted (in which the imposed SSTs have been shifted by a year so there is an out-of-phase relaxation of the winds with respect to the SSTs). The annual-mean difference of precipitation between QBOW and E phases from the three experiments are compared with GPCP differences in Fig. 7.15. The AMIP Nudged ensemble-mean matches closely the results of GPCP, characterised by an El Niño pattern in the Pacific Ocean, a weaker Atlantic ITCZ and a zonal gradient of precipitation in the Indian Ocean during QBOW compared to QBOE.

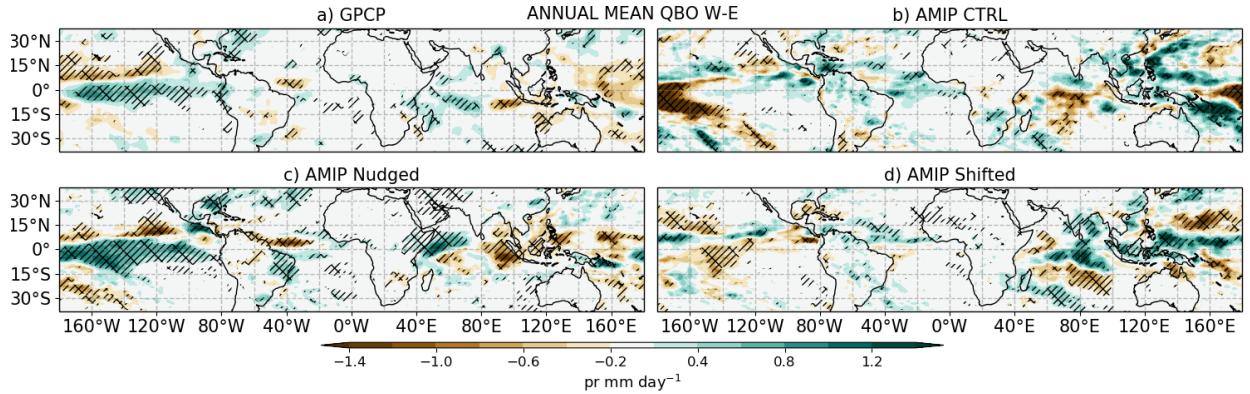

Figure 7.15: Annual-mean precipitation response (QBO W-E) in (a) GPCP, and atmosphere-only experiments: (b) AMIP CTRL, (c) AMIP Nudged and (d) AMIP Shifted.

In contrast, the AMIP Control and the AMIP Shifted experiments fail to reproduce the observations. A similar result is found for seasonal-mean composite differences (not shown).

It is interesting to compare the results of the AMIP Control experiment (Figure 7.15b) with the corresponding CMIP6 coupled GC3 N96-pi results (Figure 7.2b) which reproduced the observations reasonably well, albeit with reduced amplitude. Although we note that the CMIP6 model set-up is not entirely identical to these experiments since the model configuration is slightly different, the major difference between them is the lack of a coupled ocean in AMIP Control. The failure of AMIP Control to simulate the observations therefore suggests an important role for the oceans in the surface response to the QBO. Moreover, the Shifted and Nudged experiments show markedly different responses. These different responses suggest that the alignment between stratospheric winds and SSTs is key to reasonably simulate the response in AMIP Nudged.

The time-series of equatorially averaged OLR, shown in Fig. 7.16a, suggests that the nudging has not had a direct influence on the underlying tropospheric processes, especially on the characteristics of tropical deep convection. The OLR is almost indistinguishable between the three AMIP experiments and agree well with ERA5. Similar results are found for OLR averaged in the EN3.4 region (Fig. 7.16b). The correlation coefficients of the three time-series with respect to ERA5 are also very similar. Examination of the spatial OLR distributions also shows no robust differences in the Pacific between the Control and AMIP Nudged (Fig 7.16c) nor between the AMIP nudged and AMIP Shifted experiments (Fig. 7.16d). This

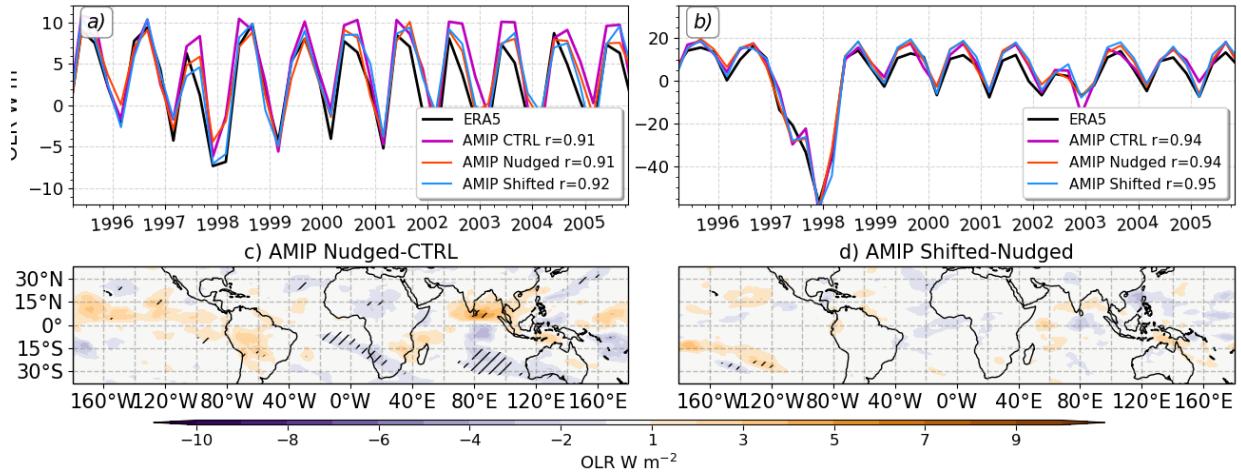

Figure 7.16: (a, b) Time-series of (a) zonal-mean equatorial [5°S - 5°N], and (b) area-averaged EN3.4 OLR in ERA5 and the three amip experiments. For each AMIP experiment the Pearson correlation coefficient between the experiment time-series and ERA5 is shown in the legend. (c) Differences in mean OLR between AMIP Nudged and Control and (d) between AMIP Shifted and Nudged. Significant (95% confidence level) differences according to a Mann-Whitney U test in (c, d) are highlighted with hatching.

result confirms that the three AMIP experiments show a similar mean state and variability of tropical OLR in the AMIP experiments, suggesting that the reasonably well reproduced response in AMIP Nudged is due to the alignment of the SSTs with the QBO winds.

Diagnostics of the overturning circulation in the AMIP Control and ERA5 are compared in Figure 7.17. The mean state of the Walker circulation is weaker in the AMIP Control simulation and exhibits an easterly bias at upper levels compared to ERA5 (Fig. 7.17c). The Walker circulation biases in the upper troposphere of the control experiments (Fig. 7.17c) are improved in the nudged experiments (Fig. 7.17d,e). Even though the relaxation is only applied above 90 hPa, significant differences between control and nudged experiments are observed for the zonal wind and streamfunction at 200 hPa near the dateline, over South America and over the Atlantic Ocean. However, no significant differences in the streamfunction or zonal wind in the lower troposphere are observed between the AMIP Shifted and Nudged experiments (Fig 7.17f). This result means that both AMIP Shifted and Nudged modify the Walker circulation to the same extent even though the nudging data is shifted by 1-year in these simulations.

This section has shown that nudging the QBO towards ERA5 zonal winds has corrected

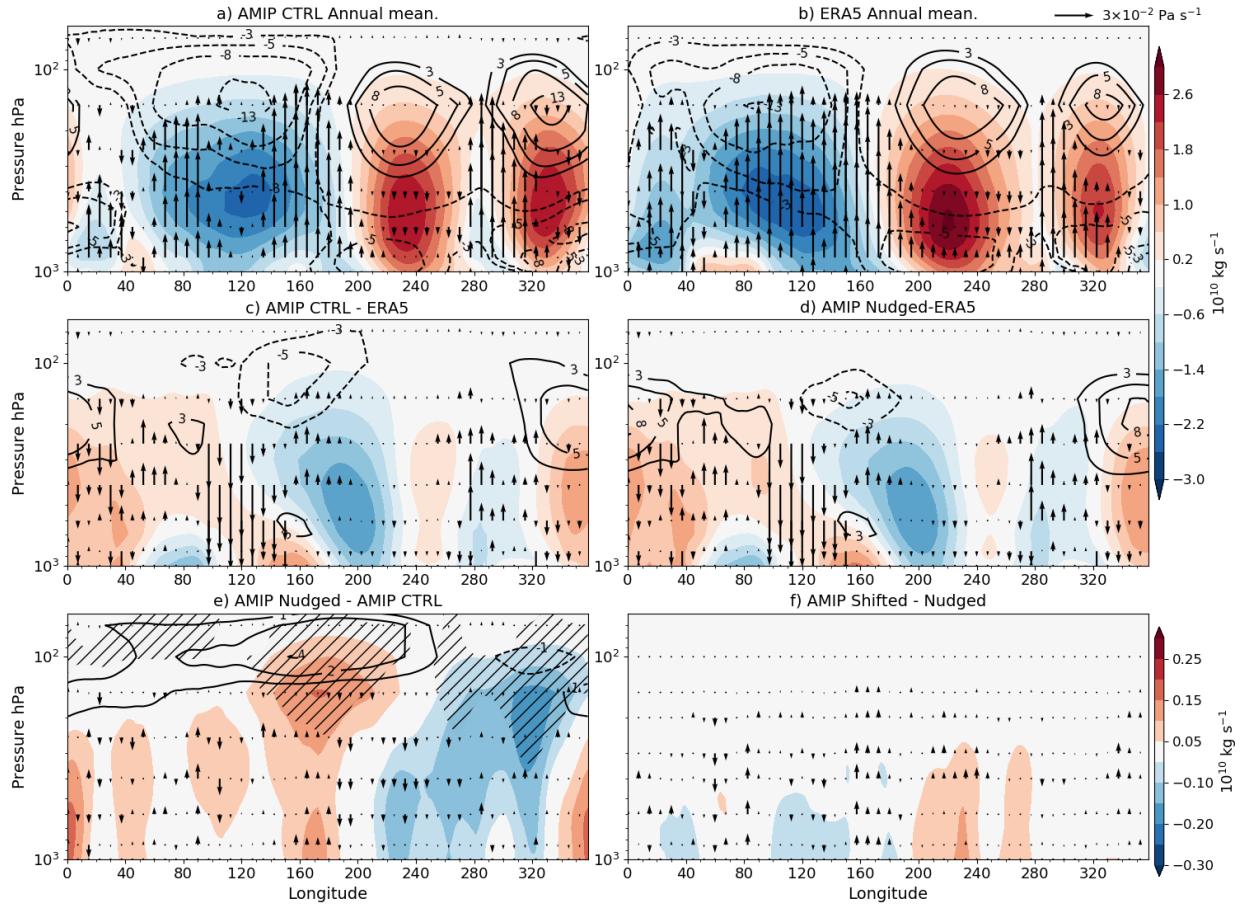

Figure 7.17: Zonal mass streamfunction (ψ in shading), zonal mean zonal wind (contours) and vertical velocity (vectors) averaged over the band 10°S - 10°N . Climatological mean in the (a) AMIP Control experiment and (b) ERA5. (c-d) show biases in the (c) Control and (d) Nudged experiments with respect to ERA5 whereas (e-f) show differences between experiments, (e) AMIP Nudged-Control and (d) AMIP Shifted-Nudged. Note that the colorbar and scale of the vectors changes are different between (a-d) and (e-f). In (e-f), significant differences (95% confidence level according to a Mann-Whitney two-sided test) in the streamfunction are highlighted with hatching.

the bias in lower stratospheric winds (Figure 7.14) which has also improved the upper-level tropical overturning circulation (Figure 7.17). However, the major result is that the precipitation response depends crucially on the SSTs, since the QBO signal in precipitation is entirely different between the AMIP Nudged and Shifted experiments. The results thus demonstrate that the QBO signal in precipitation is primarily due to the QBO signal in the underlying SSTs (which can be observed in Figures 7.4 and 7.18a). The direct influence of the improved QBO winds and temperature variability in the UTLS for tropical deep convection seems to be of secondary importance relative to the SST forcing. However,

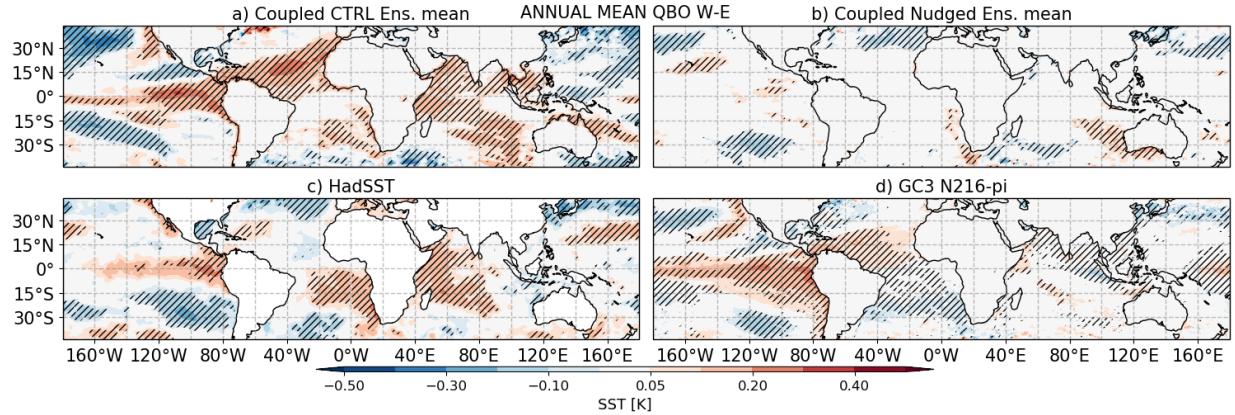

Figure 7.18: Annual mean SST [K] QBO W-E differences in (a) Coupled Control and (b) Coupled Nudged ensemble mean, and the (c) HadSST dataset and (d) GC3 N216-pi datasets. Hatching denotes significance to the 95% confidence level according to a bootstrapping with replacement test.

because the SSTs are imposed in the AMIP model configuration, the source of the QBO signal in SSTs and the nature of any feedback mechanism between the QBO and the SSTs cannot be addressed. For this reason, next we present the results from the simulations using the coupled model configuration.

7.4.2 Coupled experiments

This section describes the results from the two experiments that were performed using the coupled ocean-atmosphere configuration of the model. Two control ensemble members (Coupled Control) were performed, each of 35-years, initialised with different initial conditions (see section 7.2.4). A further six 35-year ensemble experiments (Coupled Nudged) were performed that were identical to the Coupled Control simulations except that the QBO nudging was applied in the same region of the equatorial stratosphere as in the AMIP experiments described above.

The annual mean QBO W-E difference in tropical SSTs in the ensemble-mean of the coupled control experiments (Fig 7.18a) compares reasonably well with the corresponding fields from HadSST and GC3 N216-pi. Note that the two ensemble members show notable differences in the Pacific and the ensemble-mean is dominated by the contribution from ensemble member 1. As discussed earlier (in section 7.3.2) the QBO W-E responses are characterized by warm signals in the East Pacific, and in the northern tropical Atlantic and Indian Oceans.

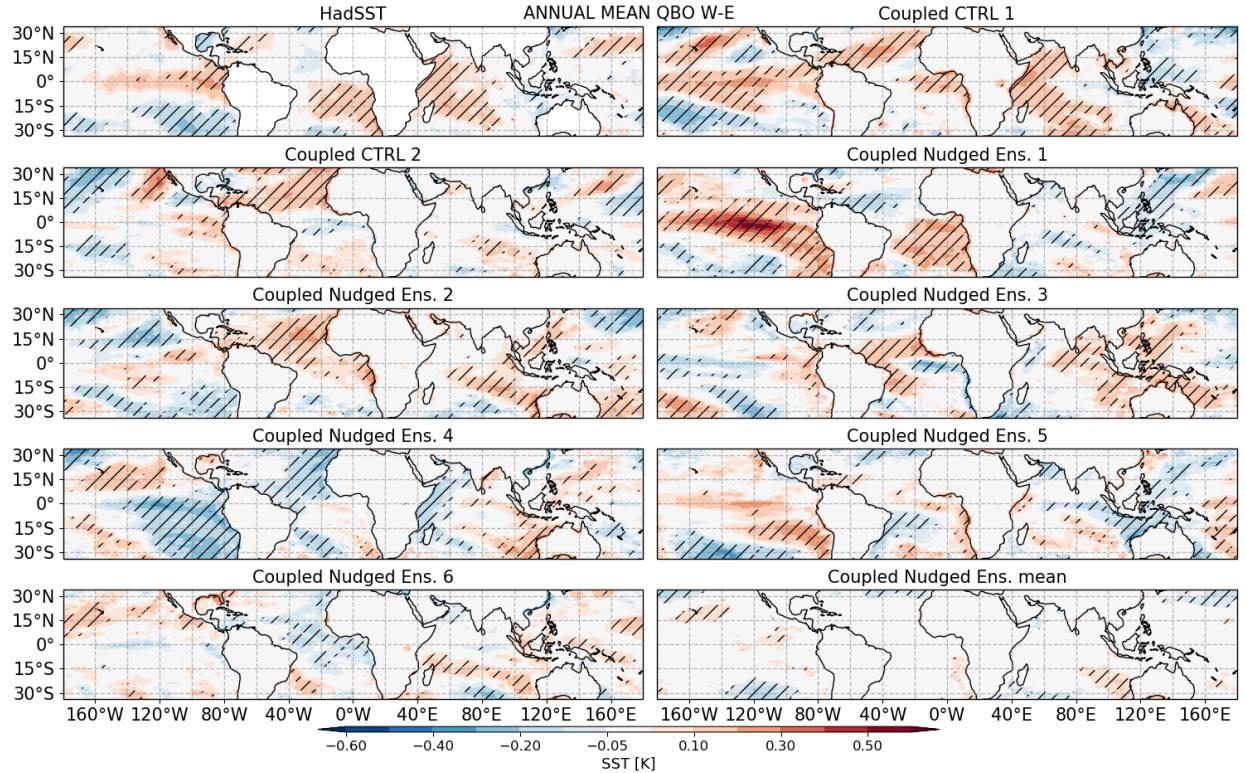

Figure 7.19: Annual-mean SST differences between QBO phases in the HadSST dataset and the individual ensemble members fromm the Coupled Control and Coupled Nudged simulations.

In contrast, the ensemble-mean of the QBO-nudged experiment, however, shows a very weak or null response (Fig. 7.18b) in all of these regions. To examine this further, Fig 7.19 shows the individual QBO W-E differences from the 6 ensemble members. The weak response in the ensemble-mean is clearly the result of very different responses from each ensemble member, which cancel out to a large extent. The individual seasonal-mean diagnostics show a similar behaviour (not shown). The results suggest that when the nudging is applied to the model a key feedback process between the QBO and SSTs has been suppressed and internal variability of the background SST conditions, which is sampled by taking different oceanic initial conditions, appears to dominate over any direct impact of the imposed QBO on the tropospheric circulation.

The precipitation response is also weaker when the nudging is applied to the coupled configuration simulations. The annual mean difference between QBO phases (Fig. 7.20) in the control experiments show two significant QBO W-E differences: a significant El Niño-like

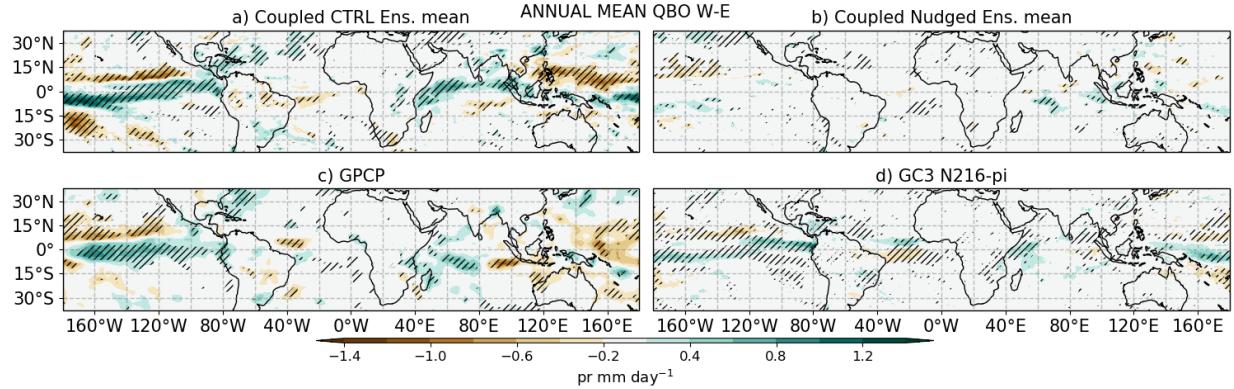

Figure 7.20: As in Fig. 7.18 but for precipitation [mm day^{-1}] using (c) GPCP as the observational dataset.

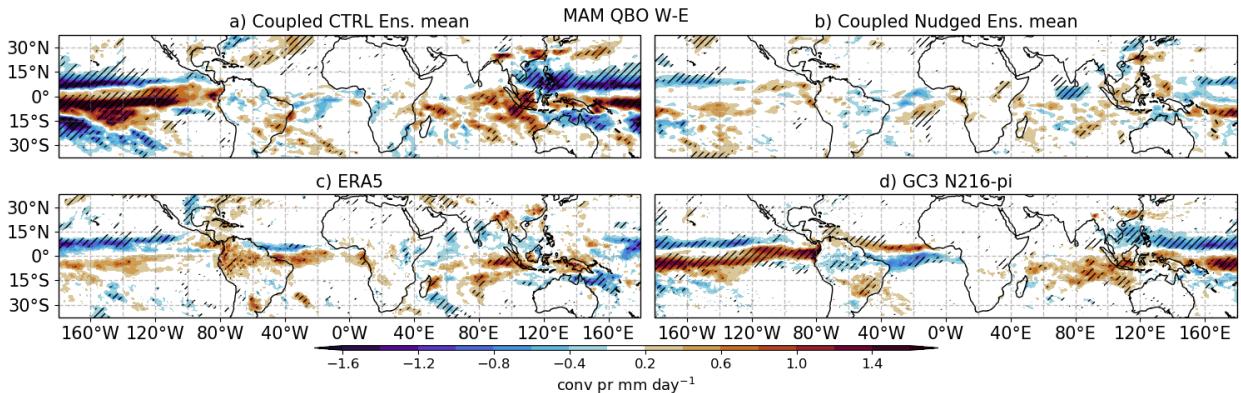

Figure 7.21: As in Figure 7.20, but for the MAM season and convective precipitation.

response over the Central and Eastern Pacific Ocean, and a wetter western Indian Ocean. These two precipitation responses are also observed in GPCP and GC3 N216-pi.

The ensemble-mean of the nudged experiments, however, shows no robust or region-wide significant differences (Fig. 7.20b). The weaker response in the ensemble-mean of the nudged experiments is also due to opposing responses found in each ensemble member which cancel out. In specific seasons, robust QBO W-E responses in convective precipitation are observed in the Control experiments, ERA5 and GC3 N216-pi, for example, a meridional dipole in the Pacific Ocean (Fig. 7.21) and a wetter eastern Indian Ocean during MAM. These results confirm that the control experiments exhibit QBO-related precipitation impacts similar to those found in the CMIP6 experiments. However, these precipitation anomalies disappear in the mean of the nudged experiments.

Robust relationships between the QBO phase, and IOD and ENSO indices are also

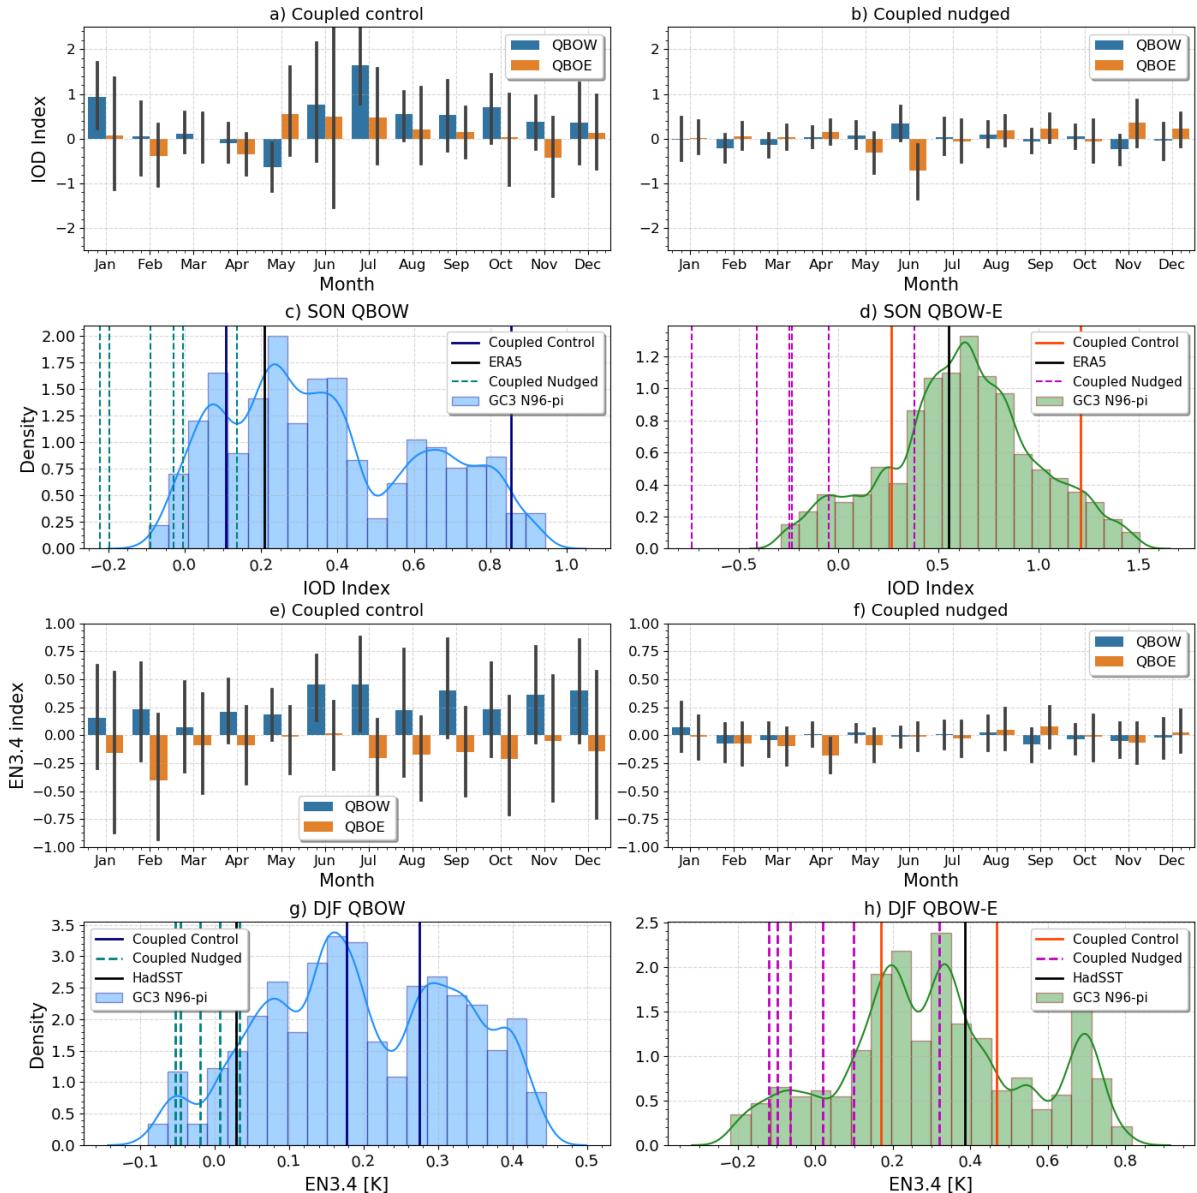

Figure 7.22: (a, b) Monthly-mean convective precipitation IOD index [mm day^{-1}] in coupled (a) control and (b) nudged ensemble-means separated by QBO phase. (c, d) Probability density functions (PDFs) of the IOD convective precipitation index for (c) the mean SON during QBOW months and (d) the SON difference between QBO W-E. The PDF is obtained from the 500 yrs of the GC3 N96-pi by bootstrapping 10,000 times into 35-yr periods and obtaining the averages and differences in each subsample. (e-f) as in (a, b) but for monthly-mean EN3.4 index [K] in the ensemble mean (e) Coupled control and (f) Coupled Nudged simulations separated by QBO phase. (g-h) as in (c-d) but for the EN3.4 index in DJF.

observed in the CMIP6 experiments (see section 7.3.3). Therefore, Figure 7.22 shows the mean values of ENSO and IOD indices from the nudged and control experiments. The coupled control experiments (Figs. 7.22a, e) show a significant difference for both IOD

and ENSO indices identical to the CMIP6 results, i.e., both indices tend to be positive under QBOW and negative under QBOE. For the IOD index, these differences are observed from Jul-to-Jan and for ENSO the differences are found almost year-round but are stronger during boreal fall and winter. However, the nudged ensemble-mean shows no relationships between these indices and the QBO phase.

To check the robustness of these results, the long CMIP6 pi-control simulations were analysed by computing QBO W-E differences of the indices for 35-yr long randomly selected periods iteratively 10,000 times. The selection of 35-yr periods is to match the length of the observed period in order to investigate how likely is it to find a QBO W-E difference value if the pi-Control simulations were of the same length as observations. This approach leads to a probability density function (PDF) of QBO W-E differences that aims to estimate the impact of internal variability on our ability to extract the QBO signal within the long pi-Control integration and to evaluate how these shorter 35-year coupled experiments fit within those distributions, with and without nudging. Figure 7.22d, for instance, shows that the QBO W-E differences in the SON IOD index are predominantly positive in the GC3 N96-pi distribution, and the differences in the two ensembles members of the control experiment are positive as well. However, the Coupled Nudged ensemble members are mostly negative and two of them fall outside the 99% low end of the PDF.

The EN3.4 index is also more frequently positive under QBOW (Fig. 7.22g) than under QBOE in the CMIP6 and control experiments. There seems to be some indication that the response from the ensemble members of the nudged experiment cancel each other to an ensemble-mean difference of 0. However the PDF of the long CMIP6 piControl does show some density of frequency for zero and weakly negative differences. This means that the long-term variability of the long piControl (illustrated by the PDF) is important for the QBO response, as in some 36 yr periods, the QBO response is null whereas in other periods the W-E difference in DJF-mean EN3.4 index is 0.8 K, indicating some degree of non-stationarity in the response which warrants further investigation.

This section shows that in the coupled configuration experiments there are notable QBO-related impacts that disappear when nudging is applied to the model. In the control experiments, impacts over the ITCZs, ENSO and the IOD, to name a few, are robust

and similar to results from observations and the longer CMIP6 integrations of the model. However, in the nudged experiments, little-to-no robust responses were observed, as each ensemble member exhibited a different response, leading to a cancellation of the differences in the ensemble-mean. The implications of these results for the stratospheric-tropospheric coupling and QBO teleconnections are discussed in the following section.

7.5 Summary and discussion

Analyses of observational records of precipitation have long suggested links between the stratospheric QBO and tropical deep convection (Collimore et al., 2003; Liess and Geller, 2012; Gray et al., 2018). However, the short available observational record (<40 years) and the confounding influence of ENSO and its teleconnections limits the robustness of any analysis seeking to explore these links and possible mechanisms of interaction between the QBO and tropical surface climate. The first part of this chapter investigates the tropical signature of the QBO in 500-year-long pre-industrial control CMIP6 experiments, with a focus on the HadGEM3 GC3.1 N216 simulation.

Composite and regression analyses were used to demonstrate that statistically significant links are simulated by the model between the QBO and several tropical climate features. Results show robust precipitation responses over the Pacific and Indian Oceans and in some seasons in the tropical north Atlantic. The QBO signal was found to be zonally asymmetric, with the more robust and largest differences found over the oceans, suggesting the possibility of SST feedback processes. The modelled QBO signals agree well with observational analyses and the length of the simulation allows for improved estimation of statistical significance and further exploration of the possible source of these signals.

The possibility of aliasing of the QBO and ENSO signals and their interaction was extensively explored in the model simulations. When only ENSO-neutral years are analysed, the QBO signal remains essentially unchanged, ruling out the possibility of aliasing of ENSO events with the QBO phase selection. The possibility of an ENSO influence on the QBO was also considered. An influence of ENSO on the descent rate and amplitude of the QBO, via modulation of tropical wave generation, has been proposed (Schirber, 2015; Christiansen

et al., 2016). However, while the model was found to successfully simulate the well-known difference in QBO descent rates in which the QBOW phase descends more rapidly than the QBOE phase, there was no evidence for an ENSO influence on the rate of descent or amplitude of either QBO phase, in agreement with the results of Serva et al. (2020).

This analysis therefore provides evidence for a QBO influence on tropical surface climate that is not simply due to aliasing or a bias in how the QBO index is determined. However, the QBO response patterns strongly suggest that any QBO influence is likely to involve processes such as deep convection and tropical circulation patterns that are also influenced by ENSO. Potential pathways of interaction between the QBO and ENSO signals were therefore explored. While recognising that linear diagnostics are unable to provide specific evidence of cause and effects, the analysis may nevertheless identify candidate mechanisms that are worth exploring more fully.

The frequency of ENSO events in each phase of the QBO was first explored. In observations, El Niño events have been found to occur more frequently in QBOW years and La Niña events are more frequently found in QBOE years (Taguchi, 2010), suggesting a non-linear interaction of ENSO with the QBO. This dependence was successfully reproduced in the model, providing supporting evidence that the observed QBO-ENSO relationship is not due to observational uncertainty. Similarly, examination of month-by-month ENSO amplitude and interannual variability in the model showed that the interaction between QBO and ENSO is far from linear, since the amplitude dependence on QBO phase was asymmetric. The non-linearity of the QBO-ENSO interaction was confirmed using precipitation composites that showed different QBO signal patterns during El Niño years compared with La Niña years.

In addition to the QBO-ENSO link, the model analysis of total precipitation also highlighted a statistically significant QBO signal in the Indian Ocean, raising the possibility of an interaction with the Indian Ocean Dipole (IOD). In boreal fall an IOD index, which measures the zonal gradient of precipitation in the Indian Ocean, was found to be anomalously positive in QBOW years and anomalously negative in QBOE years.

The analysis also confirms the previously proposed hypothesis that the QBO may influence the mean-state of the Walker circulation, which could explain the zonally asymmetric nature of the QBO signal in precipitation in the tropics (Collimore et al., 2003; Liess and Geller,

2012; Hitchman et al., 2021). The modelled Walker circulation was found to vary by up to 10% between QBO phases, even when the effect of ENSO events was taken into account. Specifically, the Walker circulation was found to be weaker during QBOW than during QBOE. In DJF, this anomaly of the overturning circulation in the Pacific is likely linked to the stronger East Pacific ITCZ, and in SON, the changes to the Walker circulation are likely linked to the ascending and descending motions that characterize the IOD.

These results are amongst the first robust pieces of evidence of QBO-tropical convection signals in a GCM. However, the methodology used does not allow us to separate the cause-effect of the diagnosed relationships. For example, these relationships could be explained by anomalous tropical wave activity that may shift the QBO phase to a preferred state, but, e.g., there was no evidence of an influence by ENSO on the downward propagation or amplitude of the QBO.

Alternatively, a top-down influence of the QBO in the tropics could explain these results. Several hypotheses have been put forth to explain a causal link between the QBO and tropical convection (Hitchman et al., 2021; Haynes et al., 2021). The most prominent hypothesis suggests that QBO-driven variations in UTLS temperature modify the upper-level static stability to the extent of affecting the height and strength of convection.

Models, including GC3 N216-pi, are known to underestimate the amplitude of the QBO signal on the UTLS static stability. Current GCMs may therefore also underestimate the impact of QBO teleconnections in the tropics. For that reason, atmosphere-only and coupled ocean-atmosphere experiments were conducted with the model stratosphere relaxed towards ERA5 in the QBO region. These experiments notably improved the QBO amplitude in the zonal wind in the lower stratosphere and thereby simulated a stronger impact of the QBO on the UTLS static stability. From this result, one could have reasonably hypothesized that stronger surface impacts would be observed in the nudged experiments relative to the control experiments.

However, the results from the AMIP experiments showed that the nudging makes little-to-no difference to the equatorial surface precipitation or OLR, even though the nudging modified (and improved) the upper-level branch of the Walker circulation and the variability of the UTLS static stability and shear, which strongly indicates a role for SST feedbacks. Indeed,

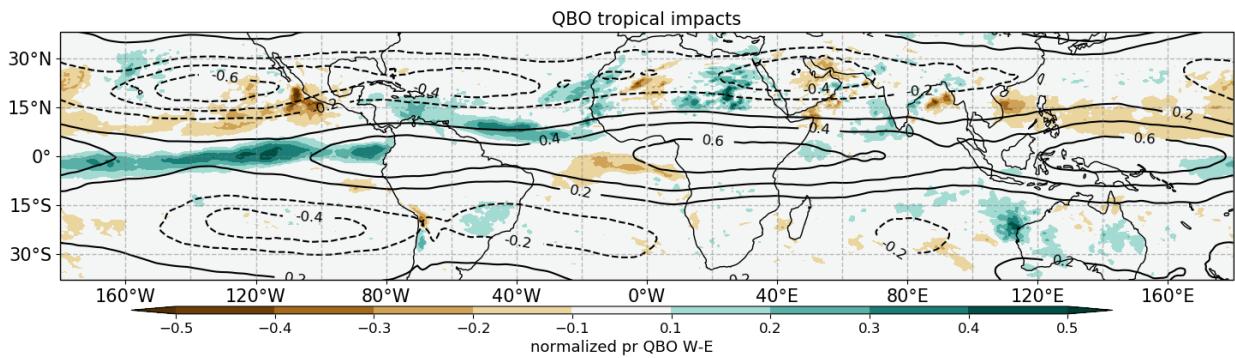

Figure 7.23: QBO W-E differences in air temperature at 100 hPa (contours) and precipitation normalized by the climatological values (shading) for the GC3 N216-pi simulation. The differences are shown for the MAM season.

while the coupled model control experiments reproduced all the major features of the QBO signals in precipitation seen in the observations and discussed in the first part of the chapter, when the QBO nudging was introduced the ensemble-mean SST and precipitation responses disappeared. Individual ensemble members of the simulations with nudging show significant responses but they cancelled in the ensemble-mean to give a null response. Furthermore, the diagnosed relationships of the QBO with ENSO and the IOD in the CMIP6 models, which are also found in the control experiments, also cancelled out in the nudged experiments.

Several different interpretations of the results from these nudging experiments are possible. First, the disappearance of the surface response when the QBO nudging is introduced could suggest that there is no downward tropical route of the QBO. Similar discussions have arisen regarding the apparent MJO-QBO relationships, with some studies suggesting that there is no causal link, and that the observed relationship is a result of statistical effects (Wang et al., 2019). However, our analysis of 3 CMIP6 pi-control simulations each of >500 years in the early part of the chapter exhaustively demonstrates that these connections are statistically robust within the model and unlikely due to chance.

Even accepting that the QBO signal in modelled precipitation is a real feature and not a statistical artifact, the results of the nudged experiments suggest that the signal is unlikely to be due to a direct downward influence of the QBO over the convective scheme of the model. The nudged AMIP experiments demonstrated that there was no direct impact of the QBO on the convective scheme of the model, since the simulated tropical OLR was not different

amongts the three AMIP experiments, in contrast to the convection-permitting fixed-SST experiments by Nie and Sobel (2015). This result suggests that either the convective scheme in the model is not sufficiently sensitive to changes in upper-level static stability, or the static stability is not the dominant causal pathway through which the QBO influences the tropical troposphere. Instead, the model results suggest that the QBO impact on tropical precipitation is primarily the result by a QBO signal in the SSTs.

It is not clear what mechanism has been disrupted by the relaxation. The nudging setup in the UM applies the relaxation at all grid-points, which not only constrains the zonal-mean component but also the wave component. This relaxation disables any feedback that involves waves and is possibly a drawback of the UM model. Further work could repeat these experiments in a spectral model with a reasonable representation of the QBO, which by nudging only the zonal-mean could better examine the interaction of tropical waves with the QBO.

Several lines of evidence in this chapter seems to contradict the UTLS static stability mechanism, at least for local scale precipitation responses. For instance, results from the first part of the chapter show that the QBO signal is characterized by zonally asymmetric responses that appear in all seasons, with much larger impacts over ocean than over land. If the UTLS static stability mechanism was a dominant process locally, then one would expect that the QBO signal should produce zonally symmetric effects or at least an impact over all regions of deep convection since there is no reason why land monsoon regions should be less affected.

Using results from the 500-year GC3 N216-pi experiment, Figure 7.23 shows that the QBO W-E differences in 100 hPa temperature are not well co-located with the surface precipitation differences. In South America and Africa, there are large differences in the 100 hPa temperatures but little corresponding differences in precipitation, whereas the Pacific shows a similar UTLS temperature signal and a stronger precipitation signal. Therefore, this suggests that the proposed UTLS static stability mechanism is unlikely to be the dominant influence by itself.

Evidence against this mechanism appears to be even more apparent in the nudged experiments, where the QBO-related variations in UTLS static stability are larger than in the free-running model experiments but the surface responses are weaker. As mentioned

above, one plausible explanation is that the convective scheme in the model is not sensitive to the static stability variations associated with the QBO (Yamazaki et al., 2020). This means that although the static stability mechanism may still be relevant in the real-world, our results suggest that within a state-of-the-art GCM the dominant factor has to be another process.

In summary, this chapter has shown that robust links exist between the QBO and the tropical troposphere in a state-of-the-art climate model. The QBO signal in tropical precipitation in the 500-yr pre-industrial control simulation compares well with the QBO signal in GPCP observations. Experiments in which the QBO zonal winds were nudged towards ERA5 reanalysis winds clearly demonstrated the importance of SST feedbacks in the QBO-precipitation relationships. Nevertheless, the origin of the QBO signal in SSTs is unclear and further research is required to understand the tropical QBO-SST-precipitation links.

Further work is needed to explore the possible influence of other modes of tropospheric variability that are relevant on QBO-frequencies, such as the tropospheric bi-ennial oscillation (TBO) (Li and Hsu, 2018). Despite of the fact that the period of the QBO in the model is longer than in observations (34 month (Schenzinger et al., 2017)), confounding influences from tropospheric variability on QBO-frequencies need to be ruled-out.

Similarly, the study of Nie and Sobel (2015) found that the QBO response in their cloud-resolving simulations was not only sensitive to the imposed SSTs but also showed a non-linear response. As their background SSTs were increased from relatively cold to relatively warm SSTs, the QBO response first increased but then reversed in sign. Further examination of the background SSTs in the control and nudged experiments could similarly evaluate a possible dependance of the precipitation response on the underlying tropical SSTs. For example, it is possible that the initial conditions of the nudged experiments are sampling different background oceanic states, resulting in different QBO W-E impacts because of low-frequency variability in tropical SSTs.

For example, the results of the 500-yr CMIP6 simulations suggest the possibility of a more subtle QBO influence that depends strongly on the phase of ENSO. The analysis showed that DJF seasonal interannual differences can depend both on ENSO and the QBO, as well as an interaction between QBOW / El Nino and between QBOE / La Nina, leading to asymmetric frequencies of ENSO events. If the QBO influence is non-linear as this suggests, so that a

positive QBO-SST feedback only operates during modest-to-strong ENSO events (for example if the QBO feedback is sensitive to the longitudinal position of the Walker circulation), then imposing a fixed QBO evolution via the nudging scheme is likely to break this feedback loop. Further model analysis to explore this non-linear relationship in our model experiments e.g. whether the amplitude of ENSO events is reduced in the nudged experiments would be of interest, as well as analysing whether the variance of tropical precipitation has changed when the nudging was applied. Future work is also discussed in the following chapter.

8

Conclusions

This chapter summarises the main findings and conclusions of this thesis, discusses the limitations of this research and potential future work.

8.1 Summary and contributions

Biases in the dynamics of the American monsoon: Assessment of GCM biases in CMIP cohorts is seldom done with an emphasis on biases relevant for the monsoons in the Americas. For this reason, less is known about the relationship between large and regional-scale biases for the AMS region compared to other monsoons. The first results chapter aims to provide a detailed account of the biases relevant for American monsoons in the CMIP6 MOHC simulations of UKESM1 and HadGEM3. A key bias found is the overestimation of precipitation in the boreal summer ITCZ in the East Pacific Ocean. Similarly, the position of the austral summer Atlantic ITCZ is biased southward in the coupled experiments, leading to biases in the dynamics of the South American monsoon. This bias is reduced in the atmosphere-only experiments suggesting a key role played by equatorial Atlantic SST biases for the representation of precipitation over land and in the ITCZ region. The dynamics and seasonality of the North American monsoon and MSD regions are relatively better represented than for the South American monsoon. The Earth System processes represented by UKESM1 do not considerably improve the representation

of the monsoon compared to HadGEM3. However, increasing the horizontal resolution and forcing the model with observed SSTs improves several biases in the large-scale dynamics and monsoon rainfall. This chapter finds that the MOHC models can simulate a bimodal signal in the seasonal cycle of precipitation, known as the Mid-summer drought, as well as relationships between the stratospheric QBO and ENSO teleconnections in the tropics. [This chapter was published as one of the earliest assessments of the AMS in the CMIP6 phase, and provides evidence both on shortcomings \(the dry Amazon bias\) and strengths \(the reasonable representation of the MSD\) of the MOHC models.](#)

A portable method to diagnose monsoon timings: Existing methods used to separate the timings of the seasonal cycle in a monsoon are usually tailored to a dataset, which complicates comparisons of multiple datasets or simulations in which the seasonal cycle or climatological precipitation is non-stationary. A wavelet transform (WT) method was developed using the Haar wavelet aiming to diagnose onset and retreat as sharp or abrupt changes to the signal of precipitation. The results obtained using the WT method are comparable to other methodologies and the portability of the method is illustrated using observational datasets, reanalysis and climate model output. Results show that the WT method reasonably captures the mean dates of onset and retreat as well as changes in the meteorological conditions associated with the monsoons in India and North America compared to existing methodologies. The method can also separate the timings of a bimodal signal by finding the dates where the drier period begins and ends. The diagnosis of the timings of the MSD simulated by the MOHC simulations using this methodology shows similar results to observations, indicating a good representation of the intricate seasonal cycle of precipitation in the MSD region by these models. [The main contribution from this chapter is the development of a portable method to diagnose onset and retreat from various datasets including climate model output and in any monsoon region which may be useful for future studies.](#)

A limited role for existing theories to explain the Mid-summer drought: Evidence from ERA5 and GCMs suggest that the SST-cloud-radiative feedback and solar declination hypotheses are not suited to explain the occurrence of a bimodal signal of precipitation in Central America and southern Mexico. Chapter 6 uses the WT method to separate the timings of the seasonal cycle and investigate closely these two hypotheses in the CMIP6 MOHC simulations and in ERA5. No evidence is found that the East Pacific SST variability drives the precipitation, as expected by the first mechanism, or that the absorbed solar radiation by the surface is the driving mechanism, as suggested in the second hypothesis. Rather, the results suggest that absorbed solar radiation by the surface co-varies with precipitation and cloudiness. The conclusion of this analysis is that the observed interannual variability or the differences in the representation of the MSD in the CMIP6 experiments cannot be explained through the arguments of these two mechanisms, suggesting other factors may be more important for the seasonality of rainfall in the region. [This chapter presents one of the most comprehensive analyses of the hypotheses that could explain the occurrence of the Midsummer Drought in southern Mexico and Central America and highlights that the predictions of the leading theories do not reasonably explain the characteristics of the MSD.](#)

The role of moisture transport for precipitation in the MSD region: The horizontal moisture transport by the zonal flow in the Caribbean, i.e., by the Caribbean Low-Level Jet (CLLJ) is found to explain some aspects of the MSD in the CMIP6 MOHC simulations and in reanalysis. The vertically integrated moisture transport and total water content decrease considerably from the period of the first peak period to the drier MSD period, and these diagnostics similarly increase in late summer during the second wet period. The moisture transport and total water content changes are explained to a certain extent by the seasonality in the CLLJ. The CLLJ variability explains to a certain extent the precipitation increases during the transition from the MSD period to the second peak period. However, the magnitude of the precipitation decrease in early summer, from the first peak to drier MSD periods is not as well explained by the CLLJ as it is by the integrated moisture transport. [The modelling evidence to support the CLLJ hypothesis in Chapter 6 adds to a](#)

large body of work that suggest a larger role for mechanical forcing rather than radiative effects for precipitation variability in the region.

The moist static energy budget provides useful insight to the MSD problem: The moist static energy (MSE) budget framework is a useful technique to investigate physical processes associated with tropical precipitation. The MSE budget is used in Chapter 6 to investigate how the MSE changes in the MSD region in the simulations and in the reanalysis and how the budget terms could be related to variations in precipitation. A strong relationship is found between the vertical advection term of the budget and precipitation, indicative of the relationship between vertical velocity and precipitation in the tropics. The horizontal advection of MSE also varies notably between the wetter and drier periods, however, there was little evidence to indicate a direct link between the magnitude of the horizontal advection term and precipitation. Both models and reanalysis suggest a limited role for surface fluxes in the variability of precipitation, although considerable biases in the surface energy budget of the models are apparent from this analysis. In short, the MSE budget framework may be used in future work to explain the seasonal cycle of precipitation and its variability. [The MSE analysis is the first instance where this budget framework was applied for the region, and the main contribution is the clear indication that this budget can be further used to investigate the variability of precipitation on the MSD time-scales.](#)

The tropical route of the QBO teleconnections in a GCM: An investigation of the tropical route of QBO teleconnections in the MOHC models was done in the last chapter of this thesis. In the long pre-industrial control experiments of CMIP6, several responses that had previously been reported in observational works were confirmed, for example, the impacts to the East Pacific ITCZ. The main findings of this analysis were impacts to the strength of the Atlantic and Pacific ITCZs, as well as wetter conditions in the Caribbean Sea and Indian Oceans during QBOW compared to QBOE. Most of these impacts were found to be seasonally varying and the season of strongest influence varied from model to model. A previously unknown relationship between the QBO phase and the zonal distribution of precipitation in the Indian Ocean was diagnosed in the GCM. This relationship is characterized by an

IOD-like response, i.e., wetter conditions in the western Indian Ocean and drier conditions in the eastern Indian Ocean during QBOW and the opposite during QBOE. Similarly, El Niño events are more frequent during QBOW and La Niña events are more frequent during QBOE in observations and in these simulations. Finally, changes to the strength of the Walker circulation were also diagnosed to be robust; this response is characterised by a weaker overturning during QBOW than during QBOE. The results in this chapter suggest a possible effect of the QBO on the ITCZs, the IOD, ENSO and the Walker circulation. [Chapter 7](#) demonstrates that the observed relationships between the QBO and tropical convection are causally linked, as multiple connections are also found in a long integration of a GCM.

QBO tropical teleconnections in a model with a nudged stratosphere: GCM experiments in which the zonal wind in the equatorial stratosphere was relaxed towards a reanalysis were performed and analysed in atmosphere-only and coupled ocean-atmosphere configurations. The atmosphere-only experiments show a limited sensitivity of the tropical circulation and convective activity to the phase of the imposed or simulated QBO. Several relationships between the QBO and convective phenomena such as the ITCZs were found in the Coupled Control experiments but these relationships dissapear in the relaxation experiments. The mean state of the Walker circulation is driven closer to observations by the relaxation technique, alleviating biases in the upper-level branch of the circulation. Yet, the variability in the Walker circulation associated with the QBO of the nudged experiments is weaker and of a different sign than in the control experiments. In short, the relaxation experiments show a stronger temperature variance in the UTLS in response to the imposed QBO shear, yet the tropical teleconnections are not stronger than in the control experiments. These results mean that the relaxation has removed relevant processes through which the QBO interacts with tropical convection. [The nudging experiments contribute to the stratospheric-tropospheric coupling research community](#), first, by pointing to the limitations of nudging, and, secondly, by providing evidence that the leading hypothesis for a QBO tropical route of teleconnections (the static stability hypothesis) may not be main cause for the observed relationships. Nevertheless, further analysis of these experiments

is required to fully understand why the tropospheric QBO signal disappears when the QBO winds are nudged instead of free-running.

8.2 Limitations and future work

The investigations presented in this thesis leave several open questions that require future work. The main limitations of each part of the research in this thesis and a discussion on how future research could address these limitations is provided below.

The general problem with GCM biases: GCM biases were recurrently found throughout this thesis as reasons for uncertainty in drawing conclusions about the simulated teleconnections and impacts in the model. From monsoon dynamics to the stratospheric-tropospheric coupling processes, biases in the representation of the mean-state and variability of tropical climate in a GCM limit our ability to draw conclusions from their output. One example is the tropical route of QBO teleconnections question, in which biases in the simulation of tropical convective features, such as the MJO, and biases in the QBO, complicate the investigation of cause and effect in stratospheric-tropospheric interactions. Future steps may use higher-resolution (<10 km) GCMs and short-term forecast configurations, which may improve several dynamical factors that have made it difficult to draw strong conclusions from Chapter 7 in this thesis.

Analysis of observational and model trends in monsoon timings: Chapter 5 shows that the WT method can be used in any observational or model data and for any monsoon so that the advantage of the method is portability. In contrast, one limitation of the method is that the WT cannot be computed in a real-time or forecasting scenario, so the method is only useful for *post hoc* processing. This limitation is due to the way the WT is computed, which requires the availability of data several months past the date of monsoon onset or retreat to compute the WT. Nevertheless, due to the advantages of the method, one further application of the method would be to diagnose observed and simulated trends in the onset and retreat dates in the global monsoon. Several regional studies exist that characterise trends in the seasonality of precipitation but due to the nature of the WT method, this

diagnosis could be done across the CMIP6 cohort of models, the existing reanalysis datasets and all the gridded precipitation datasets available. This research could provide a more comprehensive analysis of if and how the seasonality of the global monsoon is changing and whether these changes are also seen in CMIP6 models.

The diagnosis of cloud-radiative effects and other quantities from observations:

Chapter 6 uses ERA5 data to diagnose several quantities such as cloud-radiative effects (CREs) and surface fluxes that are known to be biased in reanalyses compared to satellite products or other observational datasets. Throughout the chapter, ERA5 data is used to compare with the CMIP6 models, yet the reanalysis does not assimilate and rather simulates some of the diagnostics used in the chapter. In this way, ERA5 can only be used as a best-model and not as real-world observations of the MSD. Further work could use other observational products to validate the results found in the chapter. In particular, a characterisation of the seasonality of CRE in observational datasets could provide insight to how CRE vary temporally in the rainy season and a comparison of simulated surface fluxes with observations could better assess how biased is the surface energy balance in the models in the East Pacific ITCZ.

A full moist-static energy budget: Accurate computation of the MSE budget is difficult in reanalysis and models because there is a need for high temporal resolution data in order for the budget to close. This limitation is typically addressed by computing the budget terms online within a model. An experiment using the MOHC models that computes the MSE with a high frequency would better show how the budget terms vary at each grid-point with the evolution of the rainy season. Similarly, the full ERA5 data was not used to compute the budget. A daily-mean and a coarser horizontal resolution than available were used to compute all the budget terms due to time limitations, which led to the MSE budget calculation not closing exactly. A more detailed calculation could provide a more precise quantification of how the budget variations relate to precipitation. Future steps could also investigate how the shape of the vertical profile of the vertical velocity varies with the stages of the MSD in the East Pacific and over land.

QBO teleconnections in a single model: Chapter 7 diagnoses the response of the tropical circulation and precipitation to the phase of the QBO in the MOHC CMIP6 simulations. These simulations are all from the same modelling centre and the models are all based on the UM, i.e., these simulations use the same dynamical core and share many of their parametrisation schemes and large-scale circulation biases. The teleconnections diagnosed in that chapter could also be analysed in different models of CMIP6 and differences in the properties of the simulated QBO and surface response amongst the models could point to processes that link convection and the QBO in this cohort of models. Similarly, experiments using the same model but varying the type of convective or gravity-wave schemes could also highlight which processes are most important to represent connections in the UTLS region, while also pointing to routes for model improvement.

Nudging a different model: The relaxation experiments described in Chapter 7 suggest that the nudging protocol reduced the connection between the tropical stratosphere and troposphere. Several reasons could explain these results but only future work can definitively provide an answer. Firstly, several types of nudging are possible with a GCM, for example, the nudging can be done through a relaxation of the zonal-mean field and not at all grid points. This type of relaxation would allow waves simulated in the troposphere to propagate to the stratosphere whereas the nudging implemented in this thesis would constrain the wave propagation from the troposphere. Therefore, relaxation experiments in a model that (1) has a good representation of the QBO and (2) has the capability of performing a zonal-mean nudging could be better suited to diagnose the directions of causality of the relationships between the QBO and tropical climate found in this chapter.
